UNIVERSITY OF MINNESOTA, MINNEAPOLIS, MINN.

NOTES

Action of Ethylene on Pure Starch.—It has been found that fruits and vegetables treated with ethylene have a higher sugar content than the same kind of fruits and vegetables not treated with the gas.¹

Because ripening is known to be accompanied by change of starch into sugar the attempt to change pure starch into sugar by the use of ethylene was made.

Fig. 1. ----, 10-min. boil; - · - · -, 5-min. boil; — 1-min. boil.

Dry starch (both corn and wheat starch were used) was placed in an atmosphere of ethylene at 21° and atmospheric pressure and, as shown by the Fehling test, was partially changed into a reducing sugar. The action was slow and was accompanied by a change in color from pure white to a pale, yellowish tint. No quantitative determination of the rate of conversion of dry starch was made, merely a qualitative test. Untreated starch showed no change in the same length of time. The same kind of

¹ Harvey and Regeimbal, "Physiology of Blanching Celery," *Proc. Am. Assoc. Advancement Sci.*, Washington Meeting, vol. 79, 1924.

starch, when made into an emulsion with water, was converted into sugar much more rapidly. A similar starch emulsion free from ethylene showed only a minute change even upon long boiling or upon standing for several weeks. The temperature varied from 21 to 24°. Water saturated with ethylene did not reduce Fehling solution. The starch emulsion absorbed about as much of the gas as did pure water, and no further absorption took place when the emulsion was allowed to stand, although the percentage of reducing sugar increased steadily.

Three starch emulsions of different "boiling times" but of the same concentration (1 g. of starch in 100 cc. of water) were saturated with ethylene at approximately 22° and allowed to stand. The first had been boiled one minute, the second five and the third ten minutes and all were allowed to cool to room temperature before they were saturated with the gas. The temperature varied between 20 and 24° while the emulsions were standing.

The rate of conversion of the starch to sugar was found to be affected by the time of boiling; for example, the ten-minute boil was changed more rapidly than the one-minute. The rate was slow at the beginning of the action, but such was to be expected. This "period of incubation" is especially noticeable in the data for the one-minute boil.

TABLE I
CONVERSION OF STARCH TO SUGAR

Time, hrs.	24	48	72	Fehling soln., cc.	96	120	144	168
No. 1	0.0	0.0	0.0	0.1	0.4	3.0	4.0	
No. 5	.0	.2	.5	1.2	1.9	5.0	7.0	
No. 10	.3	1.0	1.8	3.3	3.5	5.8	6.0	

No. 1 boiled one minute, No. 5 boiled five minutes, No. 10 boiled ten minutes, before saturation with ethylene. In each case a 10cc. sample of the well-stirred emulsion was used for the titration. No. 5 showed 57% of reducing sugar at the end of 168 hours, when these observations were discontinued.

The presence of the plateaus in the curve for the ten-minute boil has not been explained at the present time.

It seems demonstrated that an enzyme need not be present, as has been thought, for the conversion of starch into sugar by the action of ethylene. The presence of ethylene alone seems sufficient. The chemistry of the reactions is not known, but it is thought that the gas acts as a catalytic agent, since no absorption was noticed even upon long standing.

This work will be continued at higher temperatures and pressures.

The Boiling Point of Para-Cresol.¹—In my article on *p*-cresol,² the literature citations omitted a determination by Clemmensen³ which has just been found in his article entitled "Über eine allgemeine Methode zur Reduktion der Carbonylgruppe in Aldehyden und Ketonen zur Methylengruppe."

He describes (p. 61) the preparation of *p*-cresol from *p*-hydroxybenzaldehyde but makes no statement concerning the source of the *p*-hydroxybenzaldehyde or its purity. The product, after several distillations, finally boiled at the constant temperature of 201°, at 750 mm. pressure.

From these meager data I have calculated the boiling point at 760 mm. pressure by means of Equations 1 and 2 of my previous article. The values found are (1) 201.50° and (2) 201.54°. They afford no basis for modifying my views previously expressed and the boiling point of 202.32° given in my paper.

The object of this note is to complete the literature citations since Clemmensen's determination is one that might be indefinitely overlooked because of the title of his article.

New Fermentation Tube.—In the determination of the qualities of different micro-organisms it is of fundamental significance to know whether the micro-organism is capable of growing in oxygen-containing, oxygen-free or other atmospheres.¹ Up to the present, different bothersome processes have been in use for this purpose. It was found that it is possible to avoid

these difficulties in a simple manner through an appropriate reconstruction of the saccharimeter of Einhorn.

When one found it necessary to grow micro-organisms on a suitable nutrition medium in a nitrogen-containing or other atmosphere, it was not possible to carry out this investigation in the present form of the saccharimeter because it does not allow the passing through of another gas. If, therefore, we add a stopcock (Fig. 1) to the longer arm of this tube, it will be possible, by simultaneously inserting a single-holed rubber stopper in the shorter end of the tube, to pass through the nutrition medium and, if necessary, to keep in the space above it whatever gas is wanted. The open surface of the liquid has to be covered simultaneously with liquid paraffin. In the case of nitrogen, the purification of this gas by passage through an alkaline pyrogallol solution is not satisfactory enough for biological purposes. Such nitrogen still oxidizes reduced methylene blue and therefore it is necessary for this purpose to pass it over hot (dark, gleaming) copper spirals.

A fermentation tube constructed in this way can of course also be used as a common saccharimeter; with such a tube, a fermentation may be carried on during which the expected quantity of carbon dioxide produced exceeds several times the capacity of the long arm of the tube. A repeated simple opening of the stopcock renders this possible. It also enables one to investigate the capacity of micro-organisms for nitrogen fixation.

NEW BOOKS

Magnetism and Atomic Structure. By EDMUND C. STONER, Ph.D., Lecturer in Physics at the University of Leeds. E. P. Dutton and Company, 681 Fifth Avenue, New York City, 1926. xiii + 371 pp. 56 figs. 22.5 × 14.5 cm. Price \$5.00.

According to the author's statement, this book is to be regarded as a supplement to ordinary works on magnetism, rather than a comprehensive treatise. The general method adopted is "to give tolerably complete outlines of representative researches, and to base discussions on these. Prominence is given to work which is thought to be of most importance and lasting value, but the selection involved is necessarily arbitrary." This mode of treatment makes possible the logical discussion in a book of moderate size of those phenomena of magnetism which bear most directly upon the problems of atomic structure. A more

coherent and readable presentation of the material is thus secured than was attainable in the more comprehensive Bulletin of the National Research Council on "Theories of Magnetism" by several collaborators. Moreover, since the publication of this report, much has been done to advance our knowledge, notably, the fundamental experimental investigations of Gerlach and Stern, and the further development of the Bohr theory of atomic structure. The significance of much of the older material is now apparent in the light of the new, but one is impressed by the fact that, in spite of the vast amount of work that has been done in the field of magnetism, only a beginning has been made in the disentanglement and explanation of the complex phenomena involved. The necessarily mathematical treatment of the material may make many of the details difficult of comprehension to some readers but will not prevent their appreciation of the general significance of the relations. The correlation of information, the indication of problems for research, and the literature references should be valuable to the investigator. The author is to be congratulated on the production of a book suggestive to the specialist and informative to the general reader.

CHARLES P. SMYTH

Handbuch der Anorganischen Chemie. (Handbook of Inorganic Chemistry.) By Dr. R. ABEGG. Vol IV, first part, first half. Oxygen, Sulfur, Selenium, Tellurium and Polonium. By Dr FR AUERBACH and Dr. I. KOPPEL. S. Hirzel, Königstrasse 2, Leipzig, 1927. xii + 966 pp. 61 figs. 17 X 24 cm. Price, unbound, M. 60; bound, M. 64.

The appearance of this already long overdue instalment of the "Handbook" was still further delayed by the death of its editor and chief author, in 1925. At that time about five-sixths of the volume was in type. The task of completing it has evidently been performed with energy and dispatch by I. Koppel, its present editor.

This volume, dealing with elements of such capital importance as oxygen and sulfur, is particularly welcome, not only because it fills a serious gap in the present Handbook, but because these elements and the others of this group have not yet been reached in the new edition of the Gmelin "Handbook" or, with the exception of oxygen, in Mellor's "Treatise." It appears to adhere to the excellent traditions and high standards of the earlier volumes. It does not aim merely to collect every relevant statement in the literature, but rather to present a critical, connected and logical survey of the chemistry of these elements, illuminated by the application of the principles of theoretical and physical chemistry.

Die seltenen Erden vom Standpunkte des Atombaus. (The Rare Earths from the Point of View of Atomic Structure.) By Dr. GEORG V. HEVESY. *Struktur der Materie in Einzeldarstellungen.* V. Julius Springer, Berlin, 1927. viii + 140 pp. 15 figs. 22 × 14.5 cm. Price, unbound, Reichsmark 9; bound, Reichsmark 10.20.

This fifth of the new German monographs on the structure of matter is a worthy successor of the excellent works with which the series began. The earlier books make their appeal more exclusively to physicists and to those chemists who follow the bewildering complexities of modern spectroscopy and quantum mechanics, but the present booklet should find a wider circle of chemical readers.

The first part deals with the (Bohr) theory of the constitution of the rare-earth atoms, and the placing of the elements in the periodic table. A rapid survey of the chemical properties and the molecular volumes of the various types of compounds gives many opportunities to relate known regularities to the general features of the Bohr model. The theory is then further elaborated in line with the work of Stoner, Hund, etc., and the absorption spectra and paramagnetism of the ions are discussed in relation to the newer views.

In the second part of the book the more detailed chemistry of the elements is surveyed, including all methods of analytical determination, and the separation processes. The ionic sizes in the sense of Grimm and of Bragg, the geochemistry and the relative abundance of the elements are the next subjects treated, and the book closes with a short historical chapter.

Professor von Hevesy has made a real contribution to systematic chemistry in showing how beautifully the facts of spectroscopy and magnetism, x-rays and densities are related to the more "purely chemical" characteristics of the elements, such as relative base strengths, crystalline form, valence, etc., as soon as both types of regularities are interpreted in terms of the Bohr theory.

Professor Bohr is reported to have remarked that had there been no rare-earth group beginning with lanthanum and ceasing with cassiopeium, his theory must have been abandoned, and certainly in this group we have at once a searching test and a brilliant triumph of the qualitative aspects of that theory.

In these days of Heisenberg and Schrödinger, it is not very clear just how such intimate prying into the atom's internal affairs as the following may need to be rephrased (p. 33). "Now the 4₄ electrons move within the region where the 5₁ and 5₂ electrons are moving throughout the greater part of their paths, with the result that the added 4₄ electron is able to compensate very considerably for the effect of the simultaneous increase of one unit in the nuclear charge."

Compactly and interestingly written, von Hevesy's book is the best short account of rare-earth chemistry available today, whether one is looking merely for experimental facts or for an attempt at coördination in terms of theory.

NORRIS F. HALL

Radioaktivität. (Radio-activity.) By DR. STEFAN MEYER and DR. EGON SCHWEIDLER. Second, enlarged and partially revised edition. B. G. Teubner, Leipzig, 1927. x + 721 pp. 108 figs. 23.5 × 16.5 cm. Price, bound, RM 36.

In the introduction, the authors defend the subject of radio-activity against the charge of having reached quasi-completeness in 1916, alleging that many really new lines of attack have been laid down in subsequent years. Quantization of nuclear processes, artificial decomposition (and perhaps upbuilding) of atoms are certainly new, and there have been new radio-active elements discovered, new models proposed and much elaboration of detail.

One learns with a certain melancholy that it has been necessary to cite 6430 references in this edition, as compared with 3080 in the earlier one, and the solid, meaty pages which follow (seven hundred of them) testify that radio-activity is no longer a little corner of a subject tucked away somewhere between chemistry and physics, but a field already assuming ample proportions in its own right.

The successive chapters comprise: Historical Introduction, The Processes of Radio-active Change, The Processes of Radio-active Radiation, The Effects of Radio-active Radiations, Measurements and Methods of Measurement, The Individual Radio-active Substances, Radio-activity in Geophysics and Cosmic Physics, Appendix.

The book is valuable for its many up-to-date tables of constants, the painstaking thoroughness of its documentation, and the wide range of the subjects covered. There seem to be no important omissions. Perhaps the least valuable part is that devoted to atomic-structure theory, which is so briefly and uncertainly treated as to be practically useless. This is, of course, a book indispensable to the specialist—others may find that shorter treatments, several of which have recently appeared in English, are adequate to their needs and more convenient to use.

NORRIS F. HALL

The Evolution and Development of the Quantum Theory. By N. M. BLIGH. With a foreword by Professor MAX PLANCK. Longmans, Green and Company, 55 Fifth Avenue, New York City, 1926. 112 pp. 6 figs. 22 × 14.5 cm. Price \$3.00.

In this small book of about one hundred pages the author attempts an account of the quantum theory from its introduction by Planck up to, but not including, the beginnings of the so-called new quantum theory of Heisenberg, Born, Jordan and Schroedinger.

THEORIES OF UNIMOLECULAR GAS REACTIONS AT LOW PRESSURES

BY OSCAR KNEFLER RICE AND HERMAN C. RAMSPERGER

RECEIVED JANUARY 10, 1927

PUBLISHED JULY 5, 1927

Certain recent experiments on the decomposition of propionic aldehyde¹ show an actual falling off at low pressures in the rate of a reaction which is unimolecular at high pressures. It would seem that some kind of collision hypothesis must be used to account for activation in such a case. The old form of the collision hypothesis as developed by Langmuir,² Christiansen and Kramers,³ and Tolman⁴ appears entirely inadequate even in the case just cited.⁵ It seems possible that the explanation may be found in the suggestion, originally made by Lewis and Smith⁶ and somewhat extended since by Christiansen⁷ and by Hinshelwood and Lindemann,⁸ that the internal degrees of freedom may be of some help in causing activation.⁸

This theory may be put in several different forms, not all of which have been considered in this connection. These will be investigated, and equations for the reaction rate at low pressures will be developed, using the methods and results of classical statistical mechanics.

¹ Hinshelwood and Thompson, *Proc. Roy. Soc.*, **113A**, 221 (1926).

² Langmuir, *THIS JOURNAL*, **42**, 2201 (1920).

³ Christiansen and Kramers, *Z. physik. Chem.*, **104**, 151 (1923).

⁴ Tolman, *THIS JOURNAL*, **47**, 1524 (1925).

⁵ Hinshelwood, *Proc. Roy. Soc.*, **113A**, 230 (1926).

⁶ Lewis and Smith, *THIS JOURNAL*, **47**, 1514 (1925).

⁷ Christiansen, *Proc. Cambridge Phil. Soc.*, **23**, 438 (1926).

⁸ Since this paper was submitted, articles by Fowler and Rideal [*Proc. Roy. Soc.*, **113A**, 570 (1927)] and Thomson [*Phil. Mag.*, [7] **3**, 241 (1927)] have been received here, in which these authors have considered the internal degrees of freedom. They were attempting to explain quite a different phenomenon, and many of their assumptions run counter to ours. In so far as their treatments coincide with ours, they are similar also to the earlier work of Hinshelwood and Christiansen.

General Considerations

There seems to be some ambiguity over the definition of heat of activation. We shall define it as the minimum energy that a molecule must possess in order that it may decompose. Only internal energy is included and not translational, since we assume with Lewis and Smith⁹ that a fast-moving molecule is no more likely to decompose than a slowly-moving one. The heat of activation is *not* to be taken as the excess over an average energy, nor as an energy term derived from the temperature coefficient of the reaction by use of the simple Arrhenius equation. In general, it is to be supposed that the energy of activation may be distributed in any manner whatsoever among the various degrees of freedom, exclusive of those concerned with the motion of translation of the molecule as a whole.

With this understanding we may now turn our attention to various possible theories.

Theory I.—The simplest possible hypothesis states that an activated molecule has a certain chance of reacting, independent of the distribution of energy among the degrees of freedom and independent of the amount it has above that necessary for activation. This is the theory which has been considered by Hinshelwood.⁵

Theory II.—It might be necessary for reaction that a *particular* degree of freedom should have a minimum energy, say ϵ_0 , but that it is able to obtain this energy, even between collisions, from other parts of the molecule.¹⁰ We shall assume that if the proper degree of freedom gets this energy, the molecule instantly decomposes. Now if the molecule *as a whole* has an energy of ϵ_0 or greater, enough of this energy *may* get to the proper degree of freedom to cause reaction to occur. A molecule is *activated*, then, if its total energy, exclusive of the translational, is at least ϵ_0 . However, the chance that it will *react* depends on the amount of energy it has in excess of ϵ_0 , for this determines the probability that enough energy will reach the right place.

Other Theories.—There may be various modifications of Theories I and II. (a) It may be that if *any one* of a number of unconnected degrees of freedom gets a certain (unshared) energy, the reaction occurs. (b) Reaction may take place if the energy becomes localized, not in a single degree of freedom, but among a few closely connected degrees of freedom, it being supposed that it makes no difference how it is distributed among this limited number of degrees of freedom. (c) It may be necessary for each of several degrees of freedom simultaneously to attain a minimum energy.

The above are typical, but other cases might readily be imagined. We shall consider chiefly Theories I and II.

⁹ Lewis and Smith, *THIS JOURNAL*, **47**, 1512 (1925).

¹⁰ Thomson (Ref. 8) also makes use of this idea.

It is to be remarked that any of the above will, of course, give a unimolecular reaction at high pressures where there is an equilibrium number of activated molecules, for the rate then depends only on the probability that something will occur within a single activated molecule.

Before we can proceed to the main part of this paper it is necessary to make a general statement concerning the method we propose to use in calculating the rate of activation. As already stated, we shall assume that interchanges of energy between molecules occur only at collisions, and we shall consider only the case in which this is the sole means of activation. Hinshelwood¹¹ shows that the rate of activation may be calculated from the rate of deactivation. This idea we intend to use, but we desire to go a little further than he does. If the pressure is high only a small fraction of the activated molecules react, most of them becoming deactivated by collisions with other molecules. The rate of activation is then obviously practically equal to the rate of deactivation. The latter may be calculated from the number of collisions of activated molecules, assuming deactivation at every collision. Now, when the pressure is low, it is no longer true that the rate of activation is equal to the rate of deactivation, because an appreciable number of the activated molecules react instead of becoming deactivated; however, this does not affect the rate of activation, and we can calculate the rate of deactivation which would exist if there were an equilibrium number of activated molecules present, and set it equal to the rate of activation. If the assumption of deactivation at every collision is not absolutely true, the last sentence does not hold, for then, by the principle of entire equilibrium, part of the source of activated molecules will be other activated molecules, whose numbers are depleted at low pressures. Now, it may be that although most of the activated molecules lose energy on collision, a small number actually gain it. One might even suppose that the entire supply of the more highly activated molecules (their number being exceedingly small) was maintained in this way from other less highly but nevertheless activated molecules. This would make no difference in the case of Theory I because of the smallness of number of the high-energy molecules. In Theory II, however, the high-energy molecules have much more tendency to react and this may more than counterbalance the other factor. It will, therefore, be necessary to make an *a posteriori* calculation to show that our assumption is justified, or to indicate how much it may lack of being true.

We may now proceed, confining ourselves throughout to the situation existing at the beginning of a reaction, where we may consider that we have a pure gas, the reaction products not yet beginning to have an effect.

¹¹ Hinshelwood, "Kinetics of Chemical Change in Gaseous Systems," Oxford, 1926, p. 127.

$$K = \int_{\epsilon_0}^{\infty} K_{\epsilon} d\epsilon = \int_{\epsilon_0}^{\infty} \frac{W_{\epsilon} b_{\epsilon} d\epsilon}{1 + b_{\epsilon} kT/(ap)} \quad (8)$$

where p/kT has been substituted for N . It will be noted that for high pressures b_{ϵ} is negligible compared to aN and we have

$$K_{\infty} = \int_{\epsilon_0}^{\infty} W_{\epsilon} b_{\epsilon} d\epsilon \quad (9)$$

By the general principles of statistical mechanics¹⁶ under the same assumptions as before

$$W_{\epsilon} d\epsilon = -\frac{1}{\left(\frac{n}{2}\right)} \left(\frac{\epsilon}{kT}\right)^{\frac{n-2}{2}} e^{-\frac{\epsilon}{kT}} \frac{d\epsilon}{kT} \quad (10)$$

We now have to evaluate b_{ϵ} .

Let us consider a number of molecules, all of which have energy between ϵ and $\epsilon + d\epsilon$, ϵ being greater than ϵ_0 . These we shall designate as molecules of Class A. There will then be a certain chance that a molecule of Class A will have an energy larger than ϵ_0 in a particular degree of freedom. We will call such a molecule a molecule of Class B. If a state of equilibrium existed, these molecules would be shifting over at a certain rate (between collisions) to molecules which, while still of Class A, would not be of Class B. Let us suppose that this rate is proportional to the number of Class B, and is independent (1) of the excess of energy in the particular degree of freedom¹⁷ and (2) of ϵ .¹⁸ Now the rate at which molecules of Class B are formed under equilibrium conditions is equal to the rate at which they revert to molecules of Class A and not of Class B, and hence is proportional to the number of Class B. If all molecules of Class B decompose, this does not affect the rate at which they are formed. Hence the rate of decomposition is proportional to the number of Class B which would normally exist in a state of equilibrium.

We have, then, to determine the fraction of all molecules which have total energy between ϵ and $\epsilon + d\epsilon$ and which would also have, if the distribution law held, one degree of freedom with energy greater than ϵ_0 .

The chance that one particular degree of freedom has an energy between ϵ_1 and $\epsilon_1 + d\epsilon_1$ is

¹⁶ Gibbs, "Elementary Principles in Statistical Mechanics," Scribner's, New York, 1902, p. 93.

¹⁷ This certainly cannot be a bad assumption to make for purposes of approximation, for the distribution law shows that the number of molecules having any appreciable excess over ϵ_0 in the particular degree of freedom is very small compared with the number having a slight excess, and hence those with a large excess do not greatly affect the calculation.

¹⁸ The shape of the curves K_{ϵ} against $\epsilon - \epsilon_0$ later to be obtained (Fig. 1) would indicate that this should be satisfactory for purposes of approximation, unless the effect of ϵ is quite marked.

$$\frac{1}{\sqrt{\pi}} \left(\frac{\epsilon_1}{kT} \right)^{-\frac{1}{2}} e^{-\frac{\epsilon_1}{kT}} \frac{d\epsilon_1}{kT} \quad (11)$$

The chance that all the rest of the degrees of freedom have among them an energy between $\epsilon - \epsilon_1 - d\epsilon_1$ and $\epsilon - \epsilon_1 + d\epsilon_1$ is

$$\frac{1}{\Gamma\left(\frac{n-1}{2}\right)} \left(\frac{\epsilon - \epsilon_1}{kT} \right)^{\frac{n-3}{2}} e^{-\frac{\epsilon - \epsilon_1}{kT}} \frac{d\epsilon + d\epsilon_1}{kT} \quad (12)$$

The product of Equations 11 and 12 is evidently greater than the probability that a molecule should have energy between ϵ and $\epsilon + d\epsilon$ and at the same time should have an energy between ϵ_1 and $\epsilon_1 + d\epsilon_1$ in one (specified) degree of freedom.¹⁹ Similarly, if we had written $d\epsilon - d\epsilon_1$, instead of $d\epsilon + d\epsilon_1$ (assuming $d\epsilon_1 < d\epsilon$), then their product would have been smaller. If $d\epsilon_1$ is small compared with $d\epsilon$, then it does not matter which way Equation 12 is written, and we may write it simply

$$\frac{1}{\Gamma\left(\frac{n-1}{2}\right)} \left(\frac{\epsilon - \epsilon_1}{kT} \right)^{\frac{n-3}{2}} e^{-\frac{\epsilon - \epsilon_1}{kT}} \frac{d\epsilon}{kT} \quad (13)$$

It is now evident that the product of Equations 11 and 13 may be integrated with respect to ϵ_1 , holding ϵ and $d\epsilon$ constant. This removes the limitation that $d\epsilon_1$ must be small compared to $d\epsilon$.²⁰

Multiplying Equations 11 and 13 and integrating with respect to ϵ_1 from ϵ_0 to ϵ will give us $\alpha W_{\epsilon} b_{\epsilon}$, where α is a constant, independent of ϵ , which will be determined later.

$$\alpha W_{\epsilon} b_{\epsilon} = \frac{1}{\sqrt{\pi} \Gamma\left(\frac{n-1}{2}\right)} \frac{e^{-\frac{\epsilon}{kT}}}{(kT)^{\frac{n}{2}}} \int_{\epsilon_0}^{\epsilon} \epsilon_1^{-\frac{1}{2}} (\epsilon - \epsilon_1)^{\frac{n-3}{2}} d\epsilon_1 \quad (14)$$

For any definite value of n the integral in this expression could be evaluated by successive integration by parts. We will, however, be content with an approximation. We see that $(\epsilon - \epsilon_1)^{(n-3/2)}$ varies much more rapidly, assuming n to be fairly large, than $\epsilon_1^{-1/2}$, and that the important part of the integrand is the part where ϵ_1 is small. We therefore write as an approximation

$$\int_{\epsilon_0}^{\epsilon} \epsilon_1^{-\frac{1}{2}} (\epsilon - \epsilon_1)^{\frac{n-3}{2}} d\epsilon_1 = \epsilon_0^{-\frac{1}{2}} \int_{\epsilon_0}^{\epsilon} (\epsilon - \epsilon_1)^{\frac{n-3}{2}} d\epsilon_1 = \frac{2\epsilon_0^{-\frac{1}{2}}}{n-1} \frac{(\epsilon - \epsilon_0)^{\frac{n-1}{2}}}{2} \quad (15)$$

¹⁹ This is seen in the following manner. Suppose the one degree of freedom to have an energy exactly ϵ_1 . Then if all the other degrees of freedom together can have an energy between $\epsilon - \epsilon_1 - d\epsilon_1$ and $\epsilon - \epsilon_1 + d\epsilon_1$, the total energy of the molecule can lie anywhere between $\epsilon - d\epsilon_1$ and $\epsilon + d\epsilon_1$. This evidently includes every molecule in which the one degree of freedom has an energy of exactly ϵ_1 and in which the total energy is between ϵ and $\epsilon + d\epsilon$, and some others besides. The same can be seen to be true for any value we choose to take between ϵ_1 and $\epsilon_1 + d\epsilon_1$.

²⁰ For treatment of a similar problem see Lorentz, "Théories Statistiques en Thermodynamique," Teubner, Leipzig and Berlin, 1916, p. 12.

To evaluate α we substitute Equation 15 in 14 and integrate with respect to ϵ from ϵ_0 to ∞ . This gives us

$$\alpha \int_{\epsilon_0}^{\infty} W_{\epsilon} b_{\epsilon} d\epsilon = \frac{2\epsilon_0^{-\frac{1}{2}} e^{-\frac{\epsilon_0}{kT}} (kT)^{\frac{1}{2}} \Gamma\left(\frac{n+1}{2}\right)}{(n-1) \sqrt{\pi} \Gamma\left(\frac{n-1}{2}\right)} \quad (16)$$

Evaluating α from Equations 16 and 9 and inserting the value in Equation 14 we have

$$W_{\epsilon} b_{\epsilon} = \frac{K_{\infty}}{\Gamma\left(\frac{n+1}{2}\right)} \frac{e^{-\frac{\epsilon-\epsilon_0}{kT}}}{kT} \left(\frac{\epsilon-\epsilon_0}{kT}\right)^{\frac{n-1}{2}} \quad (17)$$

From 17 and 10

$$b_{\epsilon} = \frac{K_{\infty} \Gamma\left(\frac{n}{2}\right)}{\Gamma\left(\frac{n+1}{2}\right)} \frac{e^{\frac{\epsilon_0}{kT}}}{(kT)^{\frac{1}{2}}} \frac{(\epsilon-\epsilon_0)^{\frac{n-1}{2}}}{\epsilon^{\frac{n-2}{2}}} \quad (18)$$

Equation 8 now becomes

$$K = \frac{K_{\infty}}{kT \Gamma\left(\frac{n+1}{2}\right)} \int_0^{\infty} \frac{e^{-\frac{\epsilon-\epsilon_0}{kT}} \left(\frac{\epsilon-\epsilon_0}{kT}\right)^{\frac{n-1}{2}}}{1 + \frac{\beta_2}{p} \frac{(\epsilon-\epsilon_0)^{\frac{n-1}{2}}}{\epsilon^{\frac{n-2}{2}}}} d(\epsilon - \epsilon_0) \quad (19)$$

where

$$\beta_2 = K_{\infty} \frac{\Gamma\left(\frac{n}{2}\right)}{\Gamma\left(\frac{n+1}{2}\right)} \sqrt{\frac{m}{\pi}} \frac{1}{4s^2} e^{\frac{\epsilon_0}{kT}}$$

This has been integrated by graphical means, and a series of curves for this purpose of the integrand, K_{ϵ} , against $\epsilon - \epsilon_0$ is shown in Fig. 1. The outer curve is the curve for infinite pressure, and the number near each curve gives the value of β'/p , where $\beta' = 3.16 \times 10^{-3} \beta_2$, ϵ and ϵ_0 being in calories per mole. The temperature used was 576° , n was taken as 11, and ϵ_0 as 54,000 calories per mole. These figures correspond to some of Hinshelwood and Thompson's experiments on propionic aldehyde. The ordinates represent the relative number of molecules having a definite energy and pressure which react in a given time. Due to the character of the function the value of the integrand decreases rapidly with high values of $\epsilon - \epsilon_0$, and although the curve theoretically extends to infinity, actually we can use a finite portion of it.

In evaluating the heat of activation from the temperature coefficient of the reaction rate in the case of Theory II, we note that here

$$\frac{d \log K_{\infty}}{dT} = \frac{\epsilon_0 + \frac{1}{2} kT}{kT^2} = \frac{U}{kT^2} \quad (20)$$

as shown by Rodebush²¹ since the rate at high pressures depends on the probability that a *single* degree of freedom have an energy greater than ϵ_0 .

We can now use the set of curves in Fig. 1 to justify the assumption we made that the actual rate of formation of molecules in a given energy range was to be calculated from the rate of loss which would exist under equilibrium conditions. The lower the pressure the less justified we would consider this assumption to be. Consider, therefore, the lowest curve of the set shown. A trifle over 11% of the area under it is to the

Fig. 1.—Curve $\beta'/p = 0$, relative area $(K/K_\infty) = 1.00$, $\beta'/p = 1/64$, $(K/K_\infty) = 0.84$; $\beta'/p = 1/16$, $(K/K_\infty) = 0.66$, $\beta'/p = 1/4$, $(K/K_\infty) = 0.44$.

right of the 11,000 mark. At $\epsilon - \epsilon_0$ equal to 5000 the concentration is about 8% of the equilibrium value. We now ask the question: How many of the molecules having an energy per mole of 65,000 cal. ($\epsilon - \epsilon_0 = 11,000$) were formed from molecules having an energy of more than 59,000 cal. per mole, and hence not present in approximately equilibrium numbers? To answer this let us use the principle of entire equilibrium and find what is the chance that a molecule of 65,000 cal. per mole energy should not lose more than 6000 cal. per mole at a collision with an average molecule (or that the other molecule should leave with more than 59,000 cal. per mole). We can do this if we assume that statistical equilibrium

²¹ Rodebush, *THIS JOURNAL*, **45**, 610 (1923).

is established between the various degrees of freedom of both molecules at a collision. If statistical equilibrium is not established at a collision, the error would be about the same for low- and high-energy molecules, and the chief result would be that only a fraction of the collisions would be effective in deactivation, which would merely mean that β_2/p would have to be multiplied by a constant factor. While this last point cannot be said to be strictly established, it is obvious that the calculation we propose to make will be a valuable indication of the validity of our assumption.

If two molecules, each having n degrees of freedom, collide, there are $2n$ degrees of freedom involved. The chance that one of the molecules with n degrees of freedom should have an energy between ϵ_2 and $\epsilon_2 + d\epsilon_2$ is

$$\Gamma\left(\frac{n}{2}\right) \left(\frac{\epsilon_2}{kT}\right)^{\frac{n-2}{2}} e^{-\frac{\epsilon_2}{kT}} \frac{d\epsilon_2}{kT} \quad (21)$$

The chance that the other molecule should have energy between $\epsilon' - \epsilon_2$ and $\epsilon' - \epsilon_2 + d\epsilon'$ is

$$\frac{1}{\Gamma\left(\frac{n}{2}\right)} \left(\frac{\epsilon' - \epsilon_2}{kT}\right)^{\frac{n-2}{2}} e^{-\frac{\epsilon' - \epsilon_2}{kT}} \frac{d\epsilon'}{kT} \quad (22)$$

By reasoning similar to that following Equations 12 and 13, the product of 21 and 22 is the probability that the total energy of the two molecules is between ϵ' and $\epsilon' + d\epsilon'$, while one of them has energy between ϵ_2 and $\epsilon_2 + d\epsilon_2$. But the chance that the two together have energy between ϵ' and $\epsilon' + d\epsilon'$ is

$$\frac{1}{\Gamma(n)} \left(\frac{\epsilon'}{kT}\right)^{n-1} e^{-\frac{\epsilon'}{kT}} \frac{d\epsilon'}{kT} \quad (23)$$

The product of Equations 21 and 22 divided by Equation 23 is the chance that if two molecules have an energy of ϵ' together, a certain one of them has an energy between ϵ_2 and $\epsilon_2 + d\epsilon_2$. Now we start with two molecules, one of which has an energy of 65,000 and the other the average energy or 9300 cal. per mole, the sum of which is ϵ' . We wish to find the chance that either of them should come out of the collision with an energy greater than 59,000 cal. per mole (ϵ''). We must double the expression [(21) \times (22)/(23)] to allow for either molecule having the energy, and integrate.

$$\frac{2\Gamma(n)}{\epsilon'^{\frac{n}{2}} \left[\Gamma\left(\frac{n}{2}\right)\right]^2} \int_{\epsilon''}^{\epsilon'} \left(\frac{\epsilon_2}{\epsilon'}\right)^{\frac{n-2}{2}} (\epsilon' - \epsilon_2)^{\frac{n-2}{2}} d\epsilon_2 \quad (24)$$

For the sake of simplicity, and since it can only cause the probability to come out greater than it should be, we will take ϵ_2/ϵ' as 1, and get

$$\frac{4\Gamma(n)}{n \left[\Gamma\left(\frac{n}{2}\right)\right]^2} \left(\frac{\epsilon' - \epsilon''}{\epsilon'}\right)^{\frac{n}{2}} = 0.081 \quad (25)$$

This seems small enough to justify our assumption as an approximation, especially when it is considered that the molecule we fixed attention on had considerably higher energy than the average reacting molecule.

Discussion of the Results in Connection with the Decomposition of Propionic Aldehyde

Either Equation 5 or 19 allows us to plot a curve for K against p . In order to fit the data one must have values of β_1 or β_2 and K_∞ which must be determined from the data, themselves. In this situation it is convenient to plot $\log K/K_\infty$ against $\log p$. In such a plot Theory I gives curves which are absolutely invariable in shape and are shifted horizontally by changes in β_1 . We can then plot the data in a similar fashion on transparent coordinate paper and attempt to effect a fit by moving the curve over the data. Since K_∞ from the data may be in error by 10 to 15% we may shift data and curves relatively to each other a short distance in the vertical as well as in the horizontal direction. The value of β_1 may be calculated from the final position of the theoretical curve, and assigning a reasonable value for s and knowing all quantities involved except n , we may find a value for n .

In Theory II a slight change in form occurs if n is changed. We must, therefore, assign a value of n in advance, and the value of β_2 which it is necessary to use in order to fit the data, and which is found by relative shifting of points and curve, as for Theory I, must agree with this value of n and the known values of the other quantities involved in the expression for β_2 ; however, because of the way in which the molecular diameter and heat of activation enter β_2 we have a leeway in this matter of several fold.

We have used the scheme outlined in constructing Fig. 2, which is for Hinshelwood and Thompson's data¹ at 576°. It will be seen that it is necessary to assign different values to K_∞ for the two theories, and that in either case the theoretical value of K_∞ is considerably higher than the highest experimental value of K . This suggests that information might be obtained not only from experiments at lower pressures, but also by experiments at higher pressures.

The value of K_∞ on Theory I is 0.020 from Fig. 2 (knowing the values of Hinshelwood and Thompson's constants). The value of β_1 used is 57 mm. of mercury. Using $s = 6 \times 10^{-8}$ and $U = 55,000$ from Hinshelwood and Thompson's temperature coefficient (see Equation 6), we find that the best value for n is 12, which checks with Hinshelwood's estimate.

The value of K_∞ on Theory II from Fig. 2 is 0.023. Using this, s as above, and $\epsilon_0 = 54,000$ (see Equation 20) we calculate that β_2 should be 1900 (n being taken as 11). The value of β_2 actually used is 4000, which is close enough, as a change of 1 in the value of n would introduce a larger discrepancy.

It will be seen that the data on the decomposition of propionic aldehyde does not allow us to decide which theory is better. We hope to be able to do this soon in the case of azomethane, experiments on which are now under way.

The curves for Theory I at different temperatures should practically coincide. On Theory II, this is not quite the case, but the effect is small (within experimental error). Hinshelwood and Thompson's data for 523°, the other temperature for which they give initial rate constants, fall similarly with reference to theoretical curves but they are displaced in the figure, a certain amount vertically corresponding approximately to the difference in the calculated²² and experimental values for high pressures in Hinshelwood and Thompson's table.²³

Fig. 2.—Theory I, - - - - -. Theory II, ———.

Other Theories

We may briefly dispose of the other theories mentioned on page 1618 as follows. One may go through a deduction similar to that given for Theory II. In each case this would seem to indicate that for a fixed total number of degrees of freedom this would give results intermediate in character to those of the two theories considered in detail, except (a) which gives exactly the same result as Theory II.

Summary

A collision theory of homogeneous gas-phase, unimolecular reactions at low pressures has been developed. Several possible forms of the theory

²² From the temperature coefficient and constants at other temperatures.

²³ Ref. 1, p. 228.

are suggested, and two of them carefully considered. These theories take account of the distribution of energy among the large number of degrees of freedom of the rather complex molecules that are known to decompose in unimolecular manner. They determine the way in which the reaction rate would be influenced by the initial pressure and can, therefore, be tested experimentally. All molecules which have a certain minimum total energy which can be calculated from the temperature coefficient are said to be activated. The rate of activation is calculated from the distribution of energy among molecules having n degrees of freedom, and by assuming that the rate of activation is equal to what the rate of deactivation would be under equilibrium conditions, and that each collision of an activated molecule results in deactivation.

When the pressure is high, most activated molecules are deactivated and but a small fraction react. At lower pressures an appreciable fraction of them react, and at very low pressures when most of the activated molecules react the reaction rate becomes very much smaller and bimolecular. By Theory I, the chance of reaction is independent of the excess of energy beyond that required for activation, and this leads to an equation of the form $K = K_{\infty} p / (p + \beta_1)$, where K is the rate constant, K_{∞} the rate constant at high pressures, p the pressure and β_1 a constant involving the number of degrees of freedom, the molecular diameter, the heat of activation, K_{∞} , etc.

Theory II requires not only that a molecule have a minimum total energy, but that such an activated molecule react only if it contains a certain minimum of energy in a particular degree of freedom. It is assumed that the internal energy may be repeatedly redistributed within the molecules between collisions. If a molecule has a large excess of energy beyond that required for activation, there will be a greater probability that this energy will get into a particular degree of freedom to cause reaction. An equation is derived which gives this probability. By fixing the number of degrees of freedom, etc., it is possible to determine the relative reaction rate at various pressures by means of a graphical integration.

The data on the decomposition of propionic aldehyde at various pressures are found to fit the theoretical curves of Theory I and Theory II about equally well. More accurate data extending over a wider pressure range are necessary to decide between the two theories.

PROMOTER ACTION IN HOMOGENEOUS CATALYSIS. IV. DECOMPOSITION OF HYDROGEN PEROXIDE BY POTASSIUM DICHROMATE ACCELERATED BY MANGANESE SALTS

BY ALFRED C. ROBERTSON¹

RECEIVED MARCH 14, 1927

PUBLISHED JULY 5, 1927

Previous studies have shown that the promotion effect noticed when two catalysts act simultaneously can be explained simply upon the basis of a change in the path of the related reactions which together produce the resultant catalytic effect, and that it is not necessary to introduce the conception of activation discussed by Pease and Taylor.² This change in the path was first demonstrated when it was shown that the copper which promoted the catalytic decomposition of hydrogen peroxide by ferric salts³ appeared as a new molecular species, namely, cupric acid. In a later study it was possible to show that the intermediate due to the catalyst decreased in concentration during promotion.⁴ This was in the system where the decomposition of hydrogen peroxide by potassium dichromate was accelerated by the presence of cobalt salts. While in this case it was not possible to identify the intermediate due to the promoter, nor to follow the formation of this substance and to show the dependence of its formation upon the disappearance of some of the intermediate due to the catalyst, nevertheless it was shown that the shape of the promotion curve followed closely an equation which had been derived governing this effect. This agreement with theory showed that catalysis obeys the law of mass action as well as do other reactions.⁴

Other promoters have been found for this reaction, so the studies were extended further to test the hypothesis. The system chosen was the one where manganous chloride acts as a promoter for potassium dichromate in decomposing hydrogen peroxide. Although the experimental results are not altogether free from complications, the interpretation of the data forms an interesting addition to and confirmation of the earlier work.

Experimental Methods

The method of experimentation⁵ is practically the same as that used in previous studies.

A special reaction flask containing the solution of hydrogen peroxide is held in the thermostat by means of a suitable clamping device. This flask is connected by small-bore glass tubing to a gas buret maintained at the same temperature as the thermostat.

¹ National Research Fellow in Chemistry.

⁵ Walton, *Z. physik. Chem.*, **47**, 188 (1904).

When thermal equilibrium is attained, a capsule containing the catalyst is dropped into the flask which is then shaken vigorously, and readings of the amount of gas evolved are made at convenient intervals. The method has proved rapid and accurate. The thermostat, which has been improved by the addition of an oscillating contact on the thermoregulator, gives a temperature regulation never varying over 0.01° , and with an average deviation of $\pm 0.003^\circ$ for an hour in spite of the large radiating surface of the water jacketed gas burets.

Promotion by Manganese Chloride at Low Concentrations.—The manganous chloride used in this study was carefully purified from the best available material. A solution of the salt was first treated with a quantity of freshly precipitated, well-washed manganous carbonate to remove iron present in large amounts. The solution was then filtered, saturated with hydrogen chloride and allowed to crystallize. This recrystallization was repeated. The salt was then crystallized from water, sucked dry upon a Büchner funnel and dried in a desiccator for several hours. This process yielded a moisture-free product which gave a clear solution neutral to litmus. The catalyst solutions were made by appropriate dilutions of a standard solution made from this material.

Fig. 1.—Concn.-time curves of typical examples.

The manganous chloride is rather a poor catalyst when used alone, giving a reaction constant of the order of 5 for a concentration of $0.04 M$. Its effect when used alone is autocatalytic, but when the salt is used as a promoter the reaction as a whole is not. Instead of being strictly of the first order, as with cobalt for a promoter, the reaction constants decrease with time in the manner shown in Fig. 1, where the logarithms of the concentration ratios are plotted as ordinates against the time in minutes as abscissas. The velocity constant for the reaction remains unchanged at first, as shown by the slope of the curve, but later decreases. The curve appears to merge into another approximately straight line.

More concordant results were obtained upon repetition of the experiments when the catalyst was added to the solution rather than the reverse. It was necessary to adopt this method although it involved a more

exacting technique and made the preparation of the catalyst solutions somewhat less accurate.

This curve was studied critically by plotting the results on a large scale. It appeared that the curve was made up of two superimposed exponential functions, which will be discussed later. This fact indicates the simultaneous presence of two first-order reactions in the catalytic process.

Catalytic Nature of the Reaction

The fact that the relationships were complicated and that several effects were present at the same time led to the suspicion that the reaction might not be truly catalytic in its outcome. This is disproved by the fact that when a mixture 0.0, 0.0005, 0.089 and 0.445 *M* in manganous chloride as promoter ran to completion (nine hours) the volumes of gas evolved were 45.10, 45.55, 45.55 and 45.65 cc., respectively. These differences are less than the usual, except for the first case where the reaction possibly had not enough time to complete its course. Since the calculated amount of oxygen necessary to oxidize one millimole per liter of bivalent metal to the quadrivalent state for a sample of 25 cc. is 0.0311 cc. of gas, it is seen that the reaction oxidizes very little manganese if any, although manganese salts are notoriously easily oxidized if the solutions are not neutral, even air effecting this change. Neither is an appreciable amount of the dichromate reduced, as shown by the color of the solution. From these facts it may be concluded that when the manganese and dichromate act together the reaction is still purely catalytic in character, these substances being left unchanged in amount and kind at the end of the reaction.

Preliminary experiments have shown that the reaction with manganese alone was somewhat autocatalytic in character. It was suspected that this effect might be due to the alkali ground off the flasks by the beads,

	∞	85.5	..	∞	83.7	..			

and measures were taken to surmount this difficulty. This was accomplished by using new, unscarred Pyrex flasks and by substituting bakelite beads and capsules for glass. These substitutes served their purpose well since this material is one of the most resistant toward chemicals. Although it was somewhat brittle, the bakelite secured for this purpose could be worked in the lathe after a few trials. The capsules were apparently unaffected by the reagents used and gave determinations which checked well with those determined in the usual way.

The data are recorded in Table I for runs made with the new equipment. It can be seen by reference to this table that the reaction between hydrogen peroxide and manganous chloride gives good first-order constants. They show but a slight trend with time and are quite small, all this in contrast to the case where the reaction is complicated by the presence of traces of alkali derived from the glass.⁶

Spitalsky also has shown that the reaction between hydrogen peroxide and potassium dichromate⁷ is purely catalytic for low concentrations of this salt.

The catalytic nature of the two component reactions has now been established and it has been shown that when the reactions occur together the reaction is still catalytic. The promotion reaction may, therefore, be considered in the same manner as in previous studies and the conception of the steady state may be utilized as has been done before.

Interpretation of the Data

As stated previously, the shape of the curve shows the presence of two superimposed first-order reactions. This condition in cases of promotion was postulated previously,⁸ but due to the nature of the reactions it has not been possible to resolve the effect into its component parts. The previous inability to divorce the effects which cause promotion is no doubt due to the fact that either the amount of the hydrogen peroxide involved in the reaction which causes the promotion was small, or the rate of this promoting reaction was only slightly faster than the reaction which it supplanted; or it may have been that both the amount of substrate involved and its rate of reaction were small. In any event the effect, as a whole, was so small that when it was superimposed upon the regular reaction it did not change the *nature* of the concentration-time curve to such an extent that it could be detected by analysis of the experimental data.

⁶ This alkali does not cause any disturbance when manganese is used in the presence of dichromate, since a small amount of the catalyst is converted into the chromate and the reaction of the solution remains unchanged. The usual concentration of alkali produced was shown by experiments performed for another purpose to be in the order of 10^{-4} *M*. This is 0.2% of the concentration of the catalyst.

⁷ Spitalsky, *Z. anorg. Chem.*, 53, 187 (1907).

⁸ Ref. 4, p. 2076.

The difficulties of resolving the promotion effect into its parts are much less formidable in the case where manganese is used as the promoter. Since the curve consists of two superimposed exponential functions, it is necessary to resolve the promotion effect into two parts. This may best be done by considering the chemical reactions involved. Therefore, the exponential expression is written in the logarithmic form commonly used by chemists, $Kt = \log f/f - x_1 + \log d/d - x_2$ and the rate expressed in the following manner

$$K = 0.4343 K \times 10^4 = \frac{F}{t} \log \frac{f}{f - x_1} + \frac{D}{t} \log \frac{d}{d - x_2} \quad (1)$$

where f is the amount of hydrogen peroxide taking part in the non-promoted reaction, d the amount of hydrogen peroxide involved in the promotion reaction and F and D are the rates of these respective reactions. Thus stated, F and D are not the same constants as those used in the previous paper. These values are related to the specific velocity constants, while those used before⁸ represent the gross effect. Here the effects causing promotion have been resolved into their components. The values x_1 and x_2 are variables comparable to x . Their significance will be apparent by looking at the sample calculation in Table II.

A number of runs was made with the concentration of the potassium dichromate fixed at 0.0005 M and with the manganese varying in concentration between 0.000001 and 0.145 M . Upon inspection it appeared that the relationships were different for the concentrations of manganese above 0.001 or 0.002 M than for those below. The treatment for the present is confined to the region between 0 and 0.0025 M in manganese. The higher concentrations will be considered later.

Upon inspecting log concentration-time graphs, similar to those shown in Fig. 1, in which various amounts of manganese were used, it appeared that the last portion of the curve had the same slope in all cases, while only the first portion showed a variation due to the promotion effect. Since the last portions of the curves for systems exhibiting promotion have the same slope as the unpromoted curve, it indicates that the primary reaction upon which the promotion effect is superimposed is not changed in rate by the presence of the promoting reaction. In preliminary studies it had been thought that this rate might be changed, but if a variation does occur it lies within the limits of experimental error. Therefore, it was assumed that the effect due to the second reaction could be obtained by subtracting the effect due to an unpromoted reaction from the observed values. Upon proceeding to calculate the results to determine the nature of this superimposed reaction a difficulty becomes apparent, since the unpromoted reaction, when followed over a long period of its life, begins to decrease in velocity although the reaction is pseudo-unimolecular and should, therefore, give good velocity constants. An

examination of Spitalsky's data shows the presence of a similar effect.⁷ This cannot be accounted for by assuming that there is a diminution of the concentration of the catalyst due to the reduction of chromium, since this effect has been shown to be absent by means of chemical analysis. Again, a direct test shows that the effect cannot be due to the solubility of the glass ground off by the beads.

In order to make the calculations of the superimposed reaction more easily interpreted, the velocity constant for the early part of the reaction was arbitrarily set at 100 (later it dropped to 90). It happens that the "break" for all the log concentration-time curves comes in the region where the reaction rate for the non-promoted reaction is still 100, so this assignment of values is quite justified. Therefore, when a line representing a reaction rate of 100 is drawn tangent to the curve passing through the points representing the experimental values and is extrapolated back to

Fig. 2.

zero time or the beginning of the reaction, the intersection of this line with the zero ordinate represents the concentration of the hydrogen peroxide, f , involved in the non-promoted reaction at the beginning. The valid assumption must be made that the velocity constant F is the same for this slightly lower concentration of hydrogen peroxide. The difference between this calculated concentration and the original concentration of hydrogen peroxide represents the amount of hydrogen peroxide going through the reactions which cause the promotion. Fig. 2 represents the operation schematically. This difference is obtained by reading off the logarithms of the extrapolated line; these values are called $\log(f - x_1)$ and are recorded in the sample calculation in Col. 3. The numbers $(f - x_1)$ are now entered in Col. 5 and subtracted from the values $(a - x)$, which are the actual concentrations. This difference is called $(d - x_2)$, where d is the concentration of hydrogen peroxide which at the beginning of the reaction enters into the promotion reaction. In order to see how the promotion reaction proceeds, the logarithms of $(d - x_2)$ are plotted against time in the same manner as for any other first order

reaction. The points fall on a straight line, the slope of which gives the reaction rate of this reaction. This slope is the D of Equation 1.

A synthetic curve formed from the constants obtained approaches the original curve for this region to less than 0.1 cc., and seldom departs farther than 0.2 cc. Considering the uncertainties attending the exact determination of the end-point and the time of mixing, the values are very satisfactory indeed. In the sample calculations shown in Table II, the calculated and observed values of $(d - x_2)$ are recorded in the last columns.

At the beginning of the reaction several minutes must be allowed for the time of mixing and the attainment of the new steady state which, however, is more rapid in this case than when cobalt is used for the promoter. It is necessary to apply a small correction in order to determine the most probable value of d . This is done by a back extrapolation on the graph of the buret readings, which gives the actual time when the reaction began. The zero time is marked on the graph of $\log(d - x_2)$ and the corrected value is then read off from the intersection of these lines.

^a d corrected to zero time, 8.9.

In Fig. 3 the values of d are plotted against the concentration of promoter in millimoles per liter. The unit of measurement is the percentage fraction of the hydrogen peroxide present at the beginning of the reaction. The maximum in the curve may have some relation to the stoichiometric ratios involved in the promotion reaction, as seems probable from previous studies with copper as a promoter for iron. At very low concentrations this system showed a maximum in the curve where the "promotion factor" was plotted against the mole fraction of total heavy metal present. This maximum corresponded to a molar ratio which agreed well with the reaction³

which was followed by a very rapid reaction which produced the accelerating effect. This concept is based on the reasonable supposition that the maximum effect should be obtained in the promotion reaction when the reactants are present in ratios corresponding to their reacting masses.⁹

Further studies were not carried out to test this point since the entrance of disturbing effects due to the presence of a reaction which predominates at higher concentrations of manganese renders such experiments of dubious value. If the maximum be at 0.001 *M*, it indicates that the intermediate is manganese with a valence of three, since the system is one using potassium dichromate at a concentration of 0.0005 *M*. Equation 3 represents the reaction; the formula of the intermediate due to the promoter is written HMnO_2 here only to depict the trivalence of manganese.

Fig. 3—Relation between *d*, *D* and the concn. of promoter.

Spectrographic studies have been made with solutions of manganese salts of varying valence.¹⁰ While these measurements are only of qualitative value they show that this method cannot be used to determine whether the valence is three or four.

The values of *D*, the reaction rate for the promotion reaction, are also plotted in Fig. 2. The scale of ordinates for this series is placed on the right of the graph. The points, excepting the first few corresponding to very low concentration of promoter, fall upon a straight line.

⁹ A maximum was not found in the promotion curve when cobalt was used as the promoter. It seems probable that this effect can only be expected when the concentration of the second intermediate due to the promoter is substantially equal to the concentration of the first intermediate due to the catalyst. Otherwise the "cyclic" nature of the reactions obscure the relationship.

¹⁰ Jaeschke and Meyer, *Z. physik. Chem.*, **83**, 281 (1913).

In those experiments, the duration of the superimposed reaction is so very short compared to the time for the others that the time of mixing becomes a large factor, and errors are to be expected. It was impossible for this reason to assign any values at all when 0.000001 *M* manganese was employed as the promoter. The variable time of mixing no doubt accounts for the variable values in this part of the curve. The slope of the line is so slight that it seems logical that it might be zero. In this case it would represent a rate which is related to the specific velocity constant of some rapid reaction such as

This is the reaction which gradually supplants the reaction

normally taking place in the non-promoted reaction; the difference between these rates of reaction is apparent in the acceleration of the reaction as a whole. The reaction represented by Equation 3 can take place because of the "transition" reaction shown in Equation 5.

This transition reaction is more rapid than the others; for the sake of simplification its rate will be considered as instantaneous until a method is found by which it may be evaluated. This assumption is necessary in order that the equation of promotion (and negative catalysis, also) may be developed quantitatively, using the concept of the steady state as the basis for calculations.

The slight slope of the line passing through the values for *D* is due to traces of the reaction which predominates at the higher concentrations of manganese; the probable interference of the reaction has been noted before.

It was not deemed necessary to study the effect of the hydrogen-ion concentration further, since an investigation of the effect of cerous salts as promoters promises to cast much more light upon this relationship.

Effect of Higher Concentrations of Manganese

It was noticed early in the investigation that the larger amounts of manganese caused the reaction to follow a much more complicated course. Therefore, a number of experiments were devised to determine more about the nature of this complicating reaction. The results are not completely reproducible and do not lend themselves to exact treatment, but they are definite enough so that valid conclusions may be drawn from them.

The first step was to determine how the promotion reaction was influenced by changes in the concentration of the hydrogen peroxide. When a reaction mixture 0.0005 *M* in potassium dichromate was promoted with

either 0.0025 or 0.02 *M* manganese, the value of *d* decreased one half or one fourth for a similar decrease in the concentration of hydrogen peroxide. However, doubling the concentration of hydrogen peroxide more than doubles the value of *d*. In both cases the value of the reaction constant *D* is substantially the same, although slightly larger with 0.02 *M* manganese.

Thus it is seen that the amount of the intermediate due to the promoter is proportional to the amount of hydrogen peroxide used. Although the reaction satisfies the equation for a first-order process, it is only pseudo-unimolecular, being actually a real second-order reaction. This fact was suspected earlier in the investigation, so care was taken that the experiments summarized in Fig. 3 were performed with hydrogen peroxide of exactly the same concentration. To accomplish this end the runs were made consecutively within a few days, during which time the sample of peroxide changed but little in concentration.

These experiments represent a steady-state condition, as shown by the fact that the results are the same with a concentration of 0.00001 *M* manganese whether the concentrated peroxide is dropped into the catalyst or whether a concentrated catalyst solution is dropped into the dilute peroxide. This condition does not exist when 0.0005 *M* manganese is used, indicating that the interfering reaction noted at higher concentrations of manganese is not a steady-state condition. Therefore all the experiments in Fig. 3 were performed with dil. hydrogen peroxide, so the effect of the interfering reaction would be minimized.

When the concentration of manganese is 0.09 *M* or more, the experimental results cannot be consistently presented as in the previous case. The reaction does not follow either a first- or second-order equation. Although the effects are very complicated and practically impossible to resolve, it seems probable that the high concentrations of intermediate due to the catalyst present before the steady state is attained, oxidize some of the manganese to a form which is reduced at a different rate from the intermediate normally formed by the manganese.

By determining the time required to decompose various fractions of the hydrogen peroxide present and taking the reciprocals of these values, it is possible to gain an insight into the course of the reactions. These values should be constant for a first-order reaction and should vary directly with a second-order reaction.

When the concentration of manganese is 0.0025 *M*, the reciprocals increase somewhat, as shown in Fig. 4. The solid lines represent 0.0025 *M* and the dotted lines 0.09 *M* manganese added to the dichromate. By this slope in the line, the presence of the complicating reaction detected before may again be noted when the concentration of manganese is 0.0025 *M*, but when 0.09 *M* is used this complicating effect, instead of being larger,

disappears. The dotted lines have practically no slope and show that by the half-life criterion the reaction is unimolecular. The reaction doubtless is not so simple. Considerations based upon spectrographic studies indicate that this reaction involves the formation and decomposition of a permanganate, and it is not to be expected that this process is unimolecular.

Fig. 4.

Spectrographic Studies

The study of the absorption spectra of solutions undergoing catalytic change has proved a powerful tool in this series of studies upon catalysis and promoter action. The first application was to show the presence of an intermediate compound formed from the catalyst and to show its chemical nature by comparison with a solution containing a substance of known composition. In another case the presence of the "promoter" in a new form was shown by this method. In a third study the "first intermediate" was shown to decrease in concentration when the catalytic change was promoted.

Optical methods are almost essential in studying intermediate compounds, which are by definition unstable, and in very few cases can be handled by the time-honored methods of the analytical chemist. Bray and Livingston¹¹ were able to isolate and measure quantitatively the intermediate in the reaction which they were studying, because of the low rate of the reactions involved.

The effect of manganous chloride upon the concentration of the intermediate due to the catalyst is very large indeed, as shown by Fig. 5. One millimole per liter reduces its concentration about 75% and 2.5 millimoles per liter practically removes all trace of the substance. The

¹¹ Bray and Livingston, *THIS JOURNAL*, **45**, 1256 (1923).

absorption now shows only the presence of potassium dichromate; there are no new absorption regions in the visible, hence the nature of the new compound of manganese cannot be determined by this method.¹⁰

When more manganese is used, for example, 0.02 *M*, the results vary with time; a steady-state condition does not prevail. In Fig. 6 the results are shown graphically. A maximum has appeared in the curve in a region which gave complete transmission when 0.0025 *M* manganese was present. This maximum corresponds almost exactly to the peak of the absorption curve for a solution of potassium permanganate. If this be true, the concentration of permanganate is about 0.000005 *M*. These results are calculated from the molar extinction coefficient for potassium permanganate obtained by other workers.¹² Their value

Fig. 5.

Effect of promoter upon absorption spectra.

Fig. 6.

agrees well with one obtained by the use of diluted volumetric solutions of known oxidimetric value. This concentration of manganese as permanganate is 2.5×10^{-4} of that added as the promoter. It appears that the formation of permanganate is the cause of the complicated behavior found in some of the reactions.

This vanishingly small concentration of intermediate, a concentration which probably could only be detected by spectrographic means, indicates the necessity of investigating very closely the course of reactions before postulating the mechanism.

This research is based upon preliminary observations noted in studies carried on at the University of Wisconsin with Professor J. H. Walton. The final work was conducted at the California Institute of Technology and was aided by a grant made to Professor A. A. Noyes by the Carnegie Institution.

¹² Hagenbach and Percy, *Helv. Chim. Acta*, **5**, 461 (1922).

Summary

1. The catalytic decomposition of hydrogen peroxide by potassium dichromate is promoted by manganese salts. The reaction does not follow a simple unimolecular course.

2. The nature of the separate reactions has been investigated and discussed. Anomalous effects due to the solubility of the glass capsules and beads were avoided by the use of bakelite.

3. The promotion effect has been shown to consist of two superimposed reactions. The results agree with the explanation previously advanced for the relations between promoter and catalyst, and by resolving the promotion effect into two parts, one related to the concentration of intermediate due to the promoter, and the other, a rate related to the specific velocity constant of the promotion reaction, the interpretation offers a striking confirmation of the earlier work.

4. The addition of promoter causes the diminution of the concentration of the first intermediate. In the simpler reaction the nature of the intermediate due to the catalyst is not known definitely. When the concentration of manganese is higher, the relation is much more complex. The intermediate in this case is probably a permanganate, as shown by spectroscopic studies.

THE ATOMIC WEIGHT OF SCANDIUM¹

BY NICOL HAMILTON SMITH

RECEIVED MARCH 15, 1927

PUBLISHED JULY 5, 1927

Introduction

Until 1919 there had been considerable doubt as to the true value for the atomic weight of scandium. The atomic weight adopted by the International Committee on Atomic Weights was 44.1, which was considered to be a representative value based upon determinations made by previous investigators. These investigators had employed the usual sulfate method and had obtained values ranging from 43.90 to 45.23 as follows. Cleve, 44.96;² Nilson, 44.13;³ Meyer and Winter, 44.94;⁴ Meyer and Goldenberg, 44.09;⁵ Meyer and Schweig, 45.23.⁶

¹ From a thesis done in cooperation with Hiram S. Lukens, and submitted by Nicol H. Smith, in partial fulfilment of the requirements for the degree of Doctor of Philosophy at the University of Pennsylvania.

³ Nilson, *ibid.*, **91**, 56, 118 (1880).

⁴ Meyer and Winter, *Z. anorg. Chem.*, **67**, 398 (1910).

⁵ Meyer and Goldenberg, *ibid.*, **102**, 12 (1912).

⁶ Meyer and Schweig, *ibid.*, **108**, 303 (1919).

Such was the information concerning the atomic weight of scandium prior to Hönigschmid's series of determinations in 1919.⁷ He determined the ratio of scandium bromide to silver and from this value obtained for the atomic weight a mean value of 45.099 ± 0.014 , his values ranging from a minimum of 45.054 to a maximum of 45.122. Hönigschmid's scandium bromide was contaminated with small quantities of scandium oxide, formed by the action of scandium bromide on the quartz apparatus at the high temperature of sublimation. (On this account he had to apply a correction to every determination.

Since scandium chloride sublimes at a much lower temperature (850°) its action on the quartz apparatus, if any, should be very slight. Therefore, the ratio of scandium chloride to silver should give a better method for the determination of the atomic weight of scandium, even though the nephelometric end-point is not as sharp as in the bromide to silver ratio.

Purification of Scandium Oxide

The scandium oxide used in this investigation was obtained from a sample of scandium oxalate on hand in this Laboratory. In order to test the purity of this oxide a preliminary determination of the atomic weight was made. From the ratio of scandium oxide to scandium sulfate, the value of 45.29 was obtained, and from the ratio of scandium chloride to silver the values of 45.16 and 45.28 were obtained. These values indicated that the scandium oxide was reasonably pure to begin with. However, this fairly pure oxide was subjected to two methods of purification: first, by means of ammonium fluoride, and second, by means of ammonium tartrate.

Purification by Means of Ammonium Fluoride.⁸—The scandium oxide obtained by igniting scandium oxalate was dissolved in redistilled hydrochloric acid and evaporated to a sirupy consistency on the water-bath in a platinum dish. The solution was then diluted and any undecomposed oxide filtered out. The clear solution was then treated with redistilled ammonium hydroxide until the excess of acid was neutralized. This clear solution was then poured slowly with stirring into a hot solution of ammonium fluoride (using 8 to 9 g. of ammonium fluoride for every gram of scandium oxide). A gelatinous precipitate of scandium fluoride is first formed but this dissolves in the excess of ammonium fluoride. The solution was kept hot for about an hour on the water-bath, then filtered through a platinum funnel into another platinum dish. The residue should consist of the fluorides of thorium and the rare earths. The filtrate contained the complex fluoride of scandium and was evaporated almost to solidification. The residue, consisting of ammonium scandium fluoride and an excess of ammonium fluoride, was then treated cautiously with concd. sulfuric acid and evaporated slowly to fuming, first on a water-bath until all hydrofluoric acid had been expelled, and then on a hot-plate, taking care to prevent bumping and loss by spattering. Owing to the large excess of ammonium sulfate, the double ammonium scandium sulfate separated out. In order to avoid using a large volume of water to take this into solution, the greater

⁷ Hönigschmid, *Z. Elektrochem.*, **25**, 91 (1919).

⁸ Meyer and Wassjuchnow, *Z. anorg. Chem.*, **86**, 257 (1914).

part of the ammonium salts was volatilized by heating. The residue was treated with a small amount of concd. hydrochloric acid and heated. The scandium sulfate could then be easily dissolved in a small amount of water.

The solution was filtered free from any basic salt and ammonia gas was passed into the clear filtrate. The precipitated scandium hydroxide was filtered and washed free from ammonia with hot, redistilled water and then dissolved in pure, redistilled nitric acid, using only a very slight excess. An excess of pure, recrystallized oxalic acid was then added to the solution, heated almost to boiling and allowed to stand for 24 hours. The precipitated scandium oxalate was then filtered on a Büchner funnel, washed with pure water, sucking dry after each washing. The dried scandium oxalate was then ignited to oxide in a platinum dish. The oxide thus obtained was pure white and was supposedly free from cerium and yttrium earths and thorium.

This purified oxide was again dissolved in redistilled hydrochloric acid, the excess of acid removed by evaporating almost to dryness and the above purification with ammonium fluoride repeated. Scandium hydroxide was again precipitated by passing ammonia into the scandium sulfate solution. After thoroughly washing the scandium hydroxide, it was transposed to oxalate by boiling with a solution of oxalic acid. After standing it was filtered, washed thoroughly, dried and ignited to oxide. The oxide obtained was pure white and after two treatments with ammonium fluoride was considered to be free from thorium. This was called Sample I.

Purification by Means of Ammonium Tartrate.⁸—The scandium oxide was dissolved in redistilled hydrochloric acid and the excess of acid removed by evaporation on the water-bath to a sirupy consistency. The solution was diluted and any excess of acid removed by neutralization with redistilled ammonium hydroxide. The neutral scandium chloride solution was then poured very slowly with vigorous stirring into 750 cc. of a 15% solution of pure ammonium tartrate. The solution was filtered, since a slight precipitate was formed. The clear filtrate was heated to boiling and freshly distilled ammonium hydroxide added to the boiling solution until the solution was faintly ammoniacal. The scandium separated as the difficultly soluble scandium ammonium tartrate, thorium remaining in solution. The solution was digested for 15 minutes and the scandium ammonium tartrate filtered out, washed with a dilute solution of ammonium tartrate, dried and ignited to scandium oxide.

This oxide was again dissolved in pure hydrochloric acid, the excess of acid removed by evaporation and the ammonium tartrate purification repeated. The pure scandium ammonium tartrate was again ignited to oxide and dissolved in hydrochloric acid. Ammonia was then passed into the hot, diluted solution and the precipitated scandium hydroxide filtered out, washed well with pure hot water, sucking dry after each washing, and then converted to oxalate by boiling with a solution of oxalic acid in slight excess. After standing for 24 hours the scandium oxalate was filtered, washed with pure water, dried and then ignited to oxide. The oxide obtained was pure white and was considered to be free from thorium. This was called Sample II.

Purification of Other Materials

Silver.—The silver used in these analyses was prepared according to the method outlined by Richards and Wells.⁹

Silver chloride was precipitated from twice recrystallized silver nitrate by redistilled hydrochloric acid and then reduced by heating with sodium hydroxide and glucose solution. The silver oxide and silver thus obtained was fused on a block of pure sugar carbon. After solution of this silver in pure, redistilled nitric acid, it was again precipi-

⁹ Richards and Wells, *THIS JOURNAL*, 27, 459 (1905).

tated by warming the solution with a solution of pure ammonium formate, prepared by passing ammonia into redistilled formic acid. The silver was then fused on a block of pure lime before the blast lamp, and the silver bars thus obtained scrubbed with sea-sand, etched with dil. nitric acid, washed with dil. ammonium hydroxide and finally with pure water. Part of this silver was dissolved in pure nitric acid and used as the electrolyte; the other part of the silver was used as the anode and pure silver was deposited on a cathode consisting of a platinum wire. The silver crystals thus obtained were washed with pure water and fused in a pure lime boat in a current of hydrogen. The buttons obtained were washed with water, scrubbed with sea-sand, then etched with dil. nitric acid, washed with dil. ammonia and finally with pure water. The buttons were then cut into suitable sizes and heated to 400° in a vacuum and kept over potassium hydroxide until used. All precautions were taken for the purification of the materials used as prescribed by Richards and Wells.

Nitric Acid.—Concd. nitric acid was redistilled, the middle portion being collected, and was tested in a nephelometer to prove the absence of halogen.

Hydrochloric Acid.—Concd. hydrochloric acid was diluted and redistilled, the middle portion being collected.

Oxalic Acid.—Oxalic acid was recrystallized thrice from solution, acidified with hydrochloric acid and finally once from pure water, centrifuging after each crystallization.

Ammonium Tartrate.—Ammonium tartrate was recrystallized twice from pure water, centrifuging after each crystallization.

Ammonium Fluoride.—The ammonium fluoride used was the purest that could be obtained. Upon examination it yielded only a trace of non-volatile material and for this reason was not subjected to a purification.

Water.—The laboratory distilled water was redistilled from alkaline permanganate. Water to be used for the nephelometer was distilled once more from dil. sulfuric acid. The condensers were made of pure block tin fitted to Pyrex flasks with constricted necks. The water was collected in Pyrex flasks and was used immediately.

Carbon Tetrachloride.—Pure carbon tetrachloride, sulfur-free, was dried for two weeks over anhydrous calcium chloride and then fractionated, collecting the middle fraction within 0.1° .

Preparation of Anhydrous Scandium Chloride

Anhydrous scandium chloride has been prepared by the action of a mixture of sulfur monochloride and chlorine on the heated oxide.¹⁰ The scandium chloride used in this investigation was prepared by the action of carbon tetrachloride on scandium oxide at a temperature of 750 – 800° . At first, attempts were made to prepare the chloride by the action of chlorine on an intimate mixture of scandium oxide and sugar carbon, but the yields of anhydrous chloride obtained were so small that this method of preparation was abandoned. The action of carbon tetrachloride on the heated oxide proceeds very smoothly. The apparatus used for the preparation of anhydrous scandium is a bottling apparatus, as shown in Fig. 1.

It consists of a quartz tube A, 36 cm. long with a side tube (c) 22 cm. long and 2 cm. wide. This quartz tube was ground to fit a Pyrex end B, 19 cm. long with two side tubes (a) 10 cm. long to hold the weighing

¹⁰ Matignon and Bourion, *Compt. rend.*, 138, 631 (1904).

bottle and (b) 12 cm. long to hold the stopper for the weighing bottle. The quartz boat containing scandium oxide was placed in the quartz side tube (c) and the air completely displaced from the apparatus by a stream of pure nitrogen. The nitrogen was prepared according to the usual laboratory method,¹¹ by passing a current of air through concd. ammonium hydroxide, then through a silica tube filled with copper spirals heated to 400–500°, then through a large quantity of dil. sulfuric acid, followed by passing through another silica tube containing copper spirals and copper oxide heated to 400–500°. The nitrogen was then passed through alkaline pyrogallate solution to remove the last traces of oxygen, through a tower containing silver nitrate solution to remove any sulfur

Fig 1

compounds and finally through two towers containing concd. sulfuric acid, two soda lime towers filled with fused potassium hydroxide and then through two long tubes containing phosphorus pentoxide. The dried nitrogen was passed through the quartz and Pyrex bottling apparatus for six hours, heating the whole apparatus to remove any traces of moisture. The stopcocks in the inlet tubes e and g were then closed and the nitrogen was by-passed through a flask containing pure, anhydrous carbon tetrachloride. The carbon tetrachloride was heated to a temperature of 50–60° and the nitrogen bubbled through it. The stream of nitrogen and carbon tetrachloride vapors was passed over the scandium oxide which was heated to about 700°. The temperature was increased to about 850° towards the end so that just a little scandium chloride sublimed from the boat to the top of the tube above the boat. Within

¹¹ Richards and Krepelka, *THIS JOURNAL*, **42**, 2221 (1920).

an hour 1.5 g. of scandium oxide could be completely converted to chloride. The complete conversion to chloride could be attained in a much shorter time by using more carbon tetrachloride and a higher temperature. At higher temperatures ($900-950^{\circ}$), however, it was found that considerable carbon tetrachloride was decomposed and carbon deposited in the quartz tube and on the scandium chloride. In order to obviate this, a lower temperature ($750-850^{\circ}$) was used, and the action of carbon tetrachloride on the oxide was continued for an hour, using only a small quantity of carbon tetrachloride. During the formation of the scandium chloride some material sublimed and was carried into the horizontal quartz tube (k) with the nitrogen stream. At the end of an hour the stopcocks in the inlet tubes e and g were opened and the stopcock in the by-pass tube through the carbon tetrachloride flask was closed. Nitrogen was passed through the entire quartz and Pyrex apparatus through the inlet tubes e, f and g, heating the entire apparatus to $150-200^{\circ}$ in order to drive out the last traces of carbon tetrachloride. The horizontal quartz tube k was heated to a high temperature to remove the small quantity of sublimed material which had come over during the formation of the chloride. Before the sublimation of the chloride this part of the quartz tube was clean and free from any sublimate which had come over during the formation of the anhydrous scandium chloride. At the end of two hours all of the carbon tetrachloride and oxidation products had been removed from the system. The stopcocks in the inlet tubes e and g were then closed, only the inlet tube f being open. The anhydrous scandium chloride in the boat in the quartz tube c was then sublimed to the horizontal quartz tube k in a current of dry nitrogen (at a temperature not exceeding $900-950^{\circ}$). Nearly all of the scandium chloride sublimed into the tube k, opposite and within an inch on either side of the tube c. Half an hour was necessary for a complete sublimation of the scandium chloride.

By heating in this manner, a fractional sublimation of the scandium chloride was carried out. The more volatile impurities such as iron and thorium, were removed during the formation of the scandium chloride. Since the temperature of sublimation did not exceed 950° any rare earth impurities would remain behind in the boat. The tube was then allowed to cool in nitrogen and the stream of nitrogen was displaced by a stream of dry air. The air was first passed through an acid permanganate solution, then through a soda lime tower filled with fused potassium hydroxide, a tower of concd. sulfuric acid, and finally through two long tubes filled with glass beads covered with phosphorus pentoxide. During the passage of the air through the system, the anhydrous chloride was transferred from the quartz tube k to the weighing bottle. This was accomplished by means of the two scoops m and o. The anhydrous scandium chloride was picked up with the scoop m and transferred to

the scoop o. Scoop o was then inserted into the weighing bottle and the chloride deposited there. The outlet tubes for the scoop handles were closed by means of a short piece of rubber tubing wired to the scoop handle. In order to facilitate the working of the scoop m, a quartz rod could be inserted at (h), by means of which the scandium chloride could be pushed into the scoop. In only one or two cases was this necessary. After a little experience in manipulating these scoops, the transfer of chloride from one scoop to another could be carried out with very little loss. Some chloride, however, is lost along the quartz tube k. Only the sublimate which collected around the outlet of Tube c was collected and placed in the weighing bottle. Any chloride which had been carried along the tube k was not collected. After passing air through Tube a for two hours, Tube b containing the stopper for the weighing bottle was inverted and the stopper pushed into the weighing bottle. The weighing bottle was then removed from the Pyrex tube and placed in a large desiccator containing phosphorus pentoxide. It was necessary to remove the stopper from the weighing bottle and clean the ground joint free from scandium chloride. After the stopper had been cleaned and inserted tightly into the weighing bottle, it was removed from the desiccator and cleaned with a damp cloth, dried carefully with a lintless cloth and allowed to stand in a desiccator in the balance room overnight. All joints were fused together throughout the system, except the Pyrex to soft glass, or Pyrex to quartz, which were ground joints.

Weighing.—All weighings were made on a Christian Becker balance No. 9 with weights standardized to 0.02 mg. according to the Richards method.¹² All weights were corrected to a vacuum, vacuum corrections being applied as follows.

	Weights	Silver	Scandium chloride	Air
Density	8.3	10.49	2.733	0.001293
Vac. corr. per g.	...	-0.000031	+0.000318

The density of scandium chloride was determined and the value 2.733 was obtained from an average of three determinations. All weighings were made by the method of substitution.

Analysis

After standing overnight in a desiccator in the balance room, the weighing bottle was placed in the balance and, after two hours, was carefully weighed. One hundred and fifty to two hundred cc. of pure, redistilled water was then frozen in a 2-liter Erlenmeyer flask with a tight-fitting ground stopper. A mixture of ammonium nitrate and crushed ice was used as a freezing mixture free from large quantities of chlorides. The stopper of the weighing bottle was then removed and the weighing bottle

¹² Richards, *THIS JOURNAL*, 22, 144 (1900).

and stopper dropped onto the ice. In order to remove the stopper it was necessary to heat gently around the ground joint. The ice was slowly melted and reaction between the anhydrous scandium chloride and water proceeded mildly. After standing for 24 hours, the stopper of the precipitation flask was removed and the solution diluted to about 1 liter. The scandium chloride dissolved in the water to a perfectly clear solution. The weighing bottle and stopper were removed, washing with much water. Silver was weighed out in the form of buttons to within 0.1–0.2 mg. of the exact equivalent, dissolved in pure, redistilled nitric acid in a flask fitted with a Richards bulb tower, diluted so that the silver was less than 0.1 *N*, and added very slowly to the chloride solution with vigorous shaking after all of the silver had been added. The solution was allowed to stand for four to six days, shaking three or four times a day. The solution was then cooled in ice for three to four hours, samples were withdrawn with a pipet and examined in the nephelometer, adding either silver nitrate or potassium chloride solutions until equilibrium was reached. The solution was allowed to stand for three to four weeks to make sure that it was in equilibrium and that no more "soaking out" had taken place. The silver nitrate and potassium chloride solutions were equivalent to 0.6 g. of silver per liter and were added from a calibrated buret. After equilibrium had been verified two or three times over a period of two weeks, 0.3 mg. of silver threw the equilibrium well over to one side. All operations involving silver chloride were carried out in the dark room lighted with a ruby light. The data for one of the analyses are given in full in order to make clear the corrections applied.

TABLE I

Wt. of ScCl_3 in air, g.	1 02924	Wt. of Ag in air	2 19894
Correction for vacuum (d, 2 733)	+0 00032	Correction for vacuum (d., 10 49)	−0 00007
Wt. of ScCl_3 in vacuum, g	1 02956	Wt. of Ag in vacuum	2 19887
		Nephelometric test	+0 00047
		Total amount of Ag in vacuum, g.	2 19934

The atomic weights of chlorine and silver were taken as 35.457 and 107.880, respectively; $\text{ScCl}_3:3\text{Ag} = 0.468120$; atomic weight of scandium, 45.132. The results are summarized in Table II.

The average results obtained using the scandium oxide purified by the ammonium fluoride method gave 45.173; the average of results obtained using the oxide purified by the ammonium tartrate method gave 45.142, which are in fairly close agreement. The average of these two values gave 45.160; although a little higher than Hönigschmid's value, 45.099, this is a fairly close check, considering the previous values for the atomic weight of scandium.

The author desires to express his sincere thanks to Dr. Hiram S. Lukens, under whose direction and kindly encouragement this work was carried out.

Summary

1. Anhydrous scandium chloride was prepared by the action of pure anhydrous carbon tetrachloride on scandium oxide.

2. A new type of bottling apparatus is described for filling the weighing bottle with scandium chloride in the presence of dry air.

3. The ratio of pure scandium chloride to pure silver was determined and the average of nine analyses gave 45.160 as the atomic weight of scandium.

THE THERMAL DECOMPOSITION OF OZONE. III. THE TEMPERATURE COEFFICIENT OF REACTION RATE

BY OLIVER R. WULF¹ AND RICHARD C. TOLMAN

RECEIVED MARCH 24, 1927

PUBLISHED JULY 5, 1927

1. Introduction

In two earlier papers,² the authors have presented the results of investigations on the thermal rate of ozone decomposition, which to a considerable extent explain the lack of agreement among the earlier researches in this field. The resulting clarification of the problem, as well as our discovery of certain improvements in technique, including in particular the discovery of a relatively reproducible source of ozone, have led us also to carry out a new investigation of the temperature coefficient of the rate of this decomposition.

¹ National Research Fellow in Chemistry.

² Wulf and Tolman, *THIS JOURNAL*, **49**, (a) 1183, (b) 1202 (1927).

As will be shown in the latter part of this paper, a knowledge of the temperature coefficient for this reaction is of particular interest, since it appears to afford definite evidence against the mechanism of ozone decomposition suggested by Jahn, which has heretofore seemed the most plausible proposal for this reaction.

2. Previous Researches on Temperature Coefficient

Before proceeding to our own experiments, we must first briefly review the results of earlier determinations of temperature coefficient, and to do this it will be most convenient to give the values obtained from previous work for the energy of activation ΔE as calculated from the Arrhenius equation in the original form

$$d \log k_2/dT = \Delta E/RT^2 \quad (1)$$

where k_2 is the specific second-order rate for the decomposition. As will be shown later, the use of an equation of precisely this form is probably not theoretically justifiable for calculating the energy of activation for this reaction, and indeed the choice of the exactly correct form would involve assumptions as to the mechanism of ozone decomposition which cannot now be made with any degree of certainty. Nevertheless, this is the form used by previous investigators in the field and will be satisfactory for the purpose of comparing results. Furthermore, we shall see later that different forms of the equation lead to values for the energy of activation which do not differ greatly.

The first calculation of temperature coefficient was made by Warburg³ from his measurements of the specific second-order rate at 100° and a total pressure of 91.5 cm. and at 126.9° and a total pressure of 98.1 cm., the difference in pressures arising from the use of oxygen at the same concentrations at the two different temperatures. He thus obtained a result which is equivalent to an energy of activation of 26,700 cal.

The next calculations were made by Clement,⁴ who measured the specific rate by the dynamic method at eight different temperatures in the range 100 to 250° and at a total pressure of 72.9 cm. These measurements would furnish an excellent determination of temperature coefficient were it not for the fact that at 100 and 127°, where from other researches we know the specific rate fairly well, Clement's values are much too high. The reason for this disagreement is not clear, but the disagreement leaves some doubt as to whether any conclusions may be drawn from these measurements as to the temperature coefficient of the normal decomposition. As already pointed out in the first of these articles,⁵ the assumptions made regarding the type of gas flow could hardly have been satisfied

³ Warburg, *Ann. Physik*, 9, 1286 (1902).

⁴ Clement, *ibid.*, 14, 341 (1904).

⁵ See Ref. 2a, where a discussion will be found of the conditions of flow necessary for the dynamic method.

in a reaction vessel of the shape Clement used, but it does not appear that this would cause high calculated values for the specific rate. If the explanation lies in the presence of positive catalyst in the ozone, the temperature coefficient of the normal decomposition might indeed be somewhat different. The value of the energy of activation calculated from Clement's measurements is 26,100 cal.

Perman and Greaves,⁶ in their study of ozone decomposition, observed the reaction at five temperatures over the range 40–120°, always at approximately 1 atm. total pressure; however, their results in general are rather discordant. The decomposition did not appear to proceed in agreement with the second order, and the change with temperature of the average values of the specific rate between temperatures of 100 and 120° was quite different than over the other three intervals. They expressed the specific rates in the units, per minute per millimeter pressure of sulfuric acid. Specific rates are, however, usually expressed in units of concentration, and since at constant concentration the pressure is a function of temperature, the specific rates calculated by them will vary with the temperature in a different way than those expressed in units of concentration. We have converted the average values of their specific rates into the units per second per mole per cubic centimeter, although the use of an average value in such cases is questionable. The values they find for the specific rate for the interval 100–120° then lead to an energy of activation of 38,300 cal. But for the intervals 80–100°, 60–80° and 40–60° the results are 25,900 cal., 26,400 cal. and 26,600 cal., respectively. It does not appear, therefore, that one may conclude much from these measurements. We are chiefly interested in the measurements at 100° and above, for in this region it seems to be easier to carry out the second-order homogeneous decomposition free from disturbing influences. However, their results over the interval 100–120° are so far removed from those over the other three lower intervals that little weight can be given to them.

Belton, Griffith and McKeown⁷ have recently measured the decomposition at 78.1 and 100° and at three different pressures. They give apparently one determination at each pressure of the specific rate at 78.1 and 100°, thus permitting three calculations of the energy of activation. The average of the three values obtained is 27,770 cal. One regrets that the complete data of a typical run are not given, in order to illustrate the extent to which each decomposition adhered to the second order. In earlier work in their Laboratory⁸ it was invariably observed that the decomposition was not of the second order, but that the calculated second-

⁶ Perman and Greaves, *Proc. Roy. Soc.*, **80A**, 353 (1908).

⁷ Belton, Griffith and McKeown, *J. Chem. Soc.*, **129**, 3153 (1926).

⁸ Griffith and McKeown, *ibid.*, **127**, 2086 (1925).

order specific rate increased somewhat over each separate decomposition. It is concluded from what they say that the deviation from second order over each of these decompositions is similar to that observed earlier.

So far as the authors are aware, there are no further measurements in the literature which permit a calculation of the temperature coefficient of this reaction rate. The most reliable previous value of the energy of activation is presumably that of Warburg, of 26,700 cal., our own value, calculated by a method which corresponds to his, has the value of 30,000 cal.

3. Experimental Procedure

In the present work the specific rate of ozone decomposition was measured at five different temperatures, using the dynamic method. The ozone used was the so-called "acid" ozone of our earlier work, which was shown in the second article of this series^{2b} to have very reproducible properties.

Fig. 1.—Decomposition apparatus.

The ozone was obtained by the electrolysis of sulfuric acid solution at high anode current density and the entire generating apparatus, including the drying train, was the same as that used in our earlier work, with the single exception of a new anode³. The old one had been rendered useless by corrosion eating through the copper cooling pipe within the glass-tube shield. The new unit was identical with the old, except that the glass tube was filled with paraffin up to and around the lead plug anode, thus preventing the electrolyte from entering the glass tube. This protected the copper cooling tube from corrosion.

The decomposition apparatus was new, and the attempt was made to reduce as far as practicable the errors inherent in the dynamic method. The apparatus is illustrated in Fig. 1. The reaction tube A consists of a double concentric helix. This was constructed of Pyrex tubing, approximately 2 meters in length and 5 mm. in bore.

³ For a description of the generating apparatus, see an article by Wulf, to appear soon elsewhere.

The measured volume of this helical reaction chamber was 44.73 cc. The connecting tubes C were of small bore. The helix was suspended in a bath B of paraffin, which was contained in a 3-liter Pyrex beaker and was heated from the outside near its base by a collar heater D. The temperature of the bath was maintained constant by a two-arm mercury regulator E, which controlled through a relay the current in the collar heater. One arm of the regulator was inside the inside coil of the helix and the other arm just outside the outside coil. A motor-driven stirrer F directed the paraffin downward through the helical coils. The thermometer G was placed so that its bulb was close to the outside helical coil and about half way down its depth. All this apparatus was mounted as a unit, independent of the 3-liter beaker, on a cover of hard wood separately supported.

The bath could be raised and lowered, the paraffin never being allowed to solidify over the decomposition apparatus because of the danger of the paraffin crushing the apparatus due to its high coefficient of expansion.

The small-bore connecting tubes of the helical reaction chamber passed upward through the cover. One of these made a T connection at H with the tube line from the ozone-generating set, this line continuing parallel to the other leading-in tube which made a right-angle bend at H, both tubes passing down an inclined surface on which the analytical absorption tubes could be raised or lowered in tracks provided for them.

The apparatus permitted the collection of a sample of gas either at J of the original oxygen-ozone mixture, or at K, this gas having suffered decomposition at the temperature of the bath for the length of time t required to pass through the helical tube. Thus a value of the initial concentration C_0 and of the concentration C after a time t were obtained. These are sufficient data to calculate the specific rate according to the expression

$$k_1 = (1/t) [(1/C) - (1/C_0)] \quad (2)$$

the order being known to be second from our earlier work. A determination of the order was, however, also made at two different temperatures in the present work.

The samples for analysis were collected in absorption tubes especially constructed for the purpose, the method of collection, however, being the same as that previously employed. Fig. 2 shows an absorption tube and the relative amount of potassium iodide solution used. Such a tube in place at I was raised quickly in the trackway over the respective delivery tube to the position L. The orifice of the delivery tube then was roughly 2 cm. above the surface of the absorbing liquid. The volume of gas collected, determined by the rate of flow and the time t_a used in collecting the sample, was considerably smaller than the volume of the tube over the liquid. The sample was thus collected by the upward displacement of the air. After the desired time t_a of collection of the absorption sample, the tube was immediately lowered to the position I, the glass stopper inserted and the tube shaken and set aside, where the absorption was allowed to continue for about an hour. The absorbed sample was analyzed by acidification and titration with standard sodium thiosulfate solution.

During the collection of a sample, the orifice of the other delivery tube was closed by a little distilled water which held itself in place by surface tension. The use of this method of analysis has been described in more detail in the second paper of this series.

Fig. 2.—
Absorption
tube.

4. Experimental Data

There are three quantities necessary for the calculations of the specific rate at a given temperature, namely: a value of the concentration of the ozone at the reaction temperature and pressure as it enters the re-

action tube; a similar value as it leaves the reaction tube, and the time required for the molecules to make the transit of the reaction tube.

To obtain these it is necessary to measure the following quantities the temperature T , the atmospheric pressure P , which is substantially that in the reaction chamber, the current I in the electrolytic ozone generator, the time t_a used for the absorption of analysis samples, and the titer value of each sample against standard sodium thiosulfate

As an illustration, the complete data for a run made on October 7th are given in Table I. C_0 values, with a few exceptions, were taken one minute after the corresponding C value, many minutes elapsing before the taking of the next C value, since sufficient time must be allowed to set up again the steady-state condition in the helical reaction tube.

TABLE I
DATA OF THE RUN OF OCTOBER 7TH
Pressure, 0.966 atm, t_a , 60 seconds

I amp	T °K	C	Titer cc of thiosulfate	C_0

^a $I = 9.85$ amp

5. Treatment of the Data

The number of moles of total gas collected in the sample for analysis is given by

$$N = t_a \frac{I}{4 \times 96,500} \left(1 - \frac{1}{3} \alpha \right) \quad (3)$$

where α is the fraction of the total oxygen in the form of ozone. This will be different for the initial and final concentrations. In this work the initial fraction of the total oxygen in the form of ozone was always of the order of 0.018. The correction term $\frac{1}{3} \alpha$ is thus so small that the error involved in assigning a rough average value to α is negligible. The value $\alpha = 0.009$ will be used in these calculations. Combining the numerical factors, we obtain

$$N = 2.583 \times 10^{-6} t_a I \quad (4)$$

The volume of this quantity of gas at reaction temperature T is

$$V = NRT/P = 2.583 \times 10^{-6} t_a IRT/P, \quad V = 2.120 \times 10^{-4} t_a II/P \quad (5)$$

The number of moles of ozone collected in this sample is evidently

$$N_{O_3} = N \times \text{titer (in cc)}/2000 \quad (6)$$

where N is the normality of the thiosulfate. Hence, the concentration

of the ozone initially and finally at reaction temperature and pressure may be computed by dividing Equation 6 by 5, giving us the expression

$$C_{O_3} = 2.359 (NP/t_r T) (\text{titer}/I) \quad (7)$$

The volume of the helical tube, as previously stated, was 44.73 cc. The small-bore connecting tubes were immersed for a distance roughly 2.5 cm. in the bath. The volume of the length immersed was small and the rate of passage of the gas through this volume was high. This tended to raise the entering ozone rapidly to temperature, and similarly the gas leaving was cooled rapidly as it passed quickly out through the long length of small-bore tubing. In using the dynamic method it is assumed that the ozone is raised immediately to reaction temperature as it enters the reaction helix, remains so as it passes through the helix, and is cooled immediately upon leaving it. The assumption is justified here, since the time of heating and cooling is small compared to the time of passage.

The time of passage through the reaction chamber may be assumed equal to the volume of the chamber divided by the volume rate of flow. The conditions necessary for the justification of this assumption are rather complicated, and as they have been treated in the second paper of this series, a discussion of them will not be repeated here. It is, however, well to repeat again that this assumption is not one which at first sight appears justifiable, and is dependent on such factors as shape of vessel and rate of flow. The present apparatus was designed in such a way that the assumption is justifiable.

The volume rate of flow in the reaction chamber is given by

$$r = (I/4 \times 96,500) \times (82.07 T/P)(1 - 1/3\alpha) \quad (8)$$

in cubic centimeters per second, where α is the average fraction of the total oxygen in the form of ozone in the reaction tube. The initial fraction varies but is of the order of 0.018 in this work. The extent of decomposition varies widely over the runs. However, the correction $1/3\alpha$ is less than 1% in any case. Hence it is sufficiently accurate to use as a constant value of the parenthesis 0.997, corresponding to $\alpha = 0.009$ as the average value in the helical tube.

The time of passage through the reaction chamber is then given by

$$t = \frac{44.73}{\frac{I}{4 \times 96,500} \frac{82.07 T}{P} 0.997} = 2.110 \times 10^5 \frac{P}{IT} \text{ seconds} \quad (9)$$

Since ozone decomposition is a change which proceeds homogeneously at a rate proportional to the square of the ozone concentration under the conditions of our experiments, the specific rate may now be calculated. By substituting into the expression

$$k_2 = (1/t_1)[(1/C_1) - (1/C_0)] \quad (10)$$

where C_0 is the concentration of ozone initially at time $t = 0$ and C_1 is this concentration after the time t_1 , we obtain

$$k_2 = \frac{I_1 T}{2.110 \times 10^5 P} \left(\frac{t_2 I_1 T}{2.359 NP \times \text{titer}_1} - \frac{t_0 I_0 T}{2.359 NP \times \text{titer}_0} \right) = \frac{2.009 \times 10^{-6} I_1 T^2 t_2}{NP^2} \left(\frac{I_1}{\text{titer}_1} - \frac{I_0}{\text{titer}_0} \right) \quad (11)$$

6. Results

Using this expression, the specific rate was calculated for the data of five runs comprising 42 sets of initial and final titer values taken at five different temperatures. The results are given in Table II in the column under the absolute temperature at which they were obtained.

TABLE II

Date	VALUES OF k_2 (CC./MOLE SEC.) $\times 10^{-4}$				
	452.2°	441.7°	431.3°	426.1°	420.9°

Av.	22.69	10.15	4.36	2.81	1.75
Av. deviation, %	3.1	2.0	3.4	3.0	4.4

The second-order character of the decomposition in the vicinity of these temperatures, as has been said above, was known from our previous work. Even though this was practically the same ozone as we had earlier found satisfactory, it seemed well to test the order in this case also, particularly because of the new decomposition vessel, in view of the possibility that the conditions of flow in the vessel used in the earlier work might not be the same as in this investigation.

In using the dynamic method the order of a reaction may be determined

TABLE III

RESULTS SHOWING SECOND-ORDER CHARACTER OF THE REACTION

T, °K.	t_1 , seconds	Titers (cc. of thiosulfate)	Titers ₁	$k_2 \times 10^{-4}$, cc./mole sec.
420.9	49.1	3.36	2.66	1.68
	48.9	3.39	2.64	1.86
	98.7	3.07	2.08	1.63
	98.7	3.19	2.10	1.67
426.1	48.5	3.90	2.61	2.75
	48.8	3.84	2.53	2.96
	96.6	3.05	1.74	2.69
	96.6	3.16	1.74	2.82

by changing either the initial concentration or the rate of flow or both. Here the rate of flow was changed, but the initial concentration also varied considerably. The results are contained in Table II, but are retabulated here with the times and titer value observed.

The agreement with the second order is evident.

7. The Temperature Coefficient and the Energy of Activation

Although the thermal decomposition of properly prepared ozone is very closely of the second order, the mechanism cannot necessarily be assumed to be bimolecular with respect to ozone because of the known inhibiting effect of oxygen, and at the present time the correct mechanism of the reaction must be regarded as unknown. This introduces difficulties into the determination of the energy of activation, since the precisely correct method of calculation would have to be determined from a knowledge of the mechanism.

For this reason we have calculated the energy of activation ΔE from each of the four following equations and obtained the results shown below,

$$k_2 = k e^{-\frac{\Delta E}{RT}} \quad ; \quad \Delta E = 30,900 \text{ cal} \quad (\text{A})$$

$$k_2 = \frac{k}{C_{O_2}} e^{-\frac{\Delta E}{RT}} \quad ; \quad \Delta E = 30,000 \text{ cal} \quad (\text{B})$$

$$k_2 = k T^{\frac{1}{2}} e^{-\frac{\Delta E}{RT}} \quad ; \quad \Delta E = 30,400 \text{ cal} \quad (\text{C})$$

$$k_2 = \frac{k}{C_{O_2}} T^{\frac{1}{2}} e^{-\frac{\Delta E}{RT}} \quad ; \quad \Delta E = 29,600 \text{ cal} \quad (\text{D})$$

k being, of course, a different constant in the four expressions. The different values of ΔE differ from each other by an amount which is somewhat greater than that corresponding to the limit of accuracy in the data.

Each of the above equations would correspond to a different set of assumptions as to the nature of the mechanism responsible for ozone decomposition, although these assumptions would not necessarily be very plausible ones.

Case A is chiefly of interest as giving the simplest empirical expression for the rate of decomposition of dilute ozonized oxygen at 1 atm. total pressure and different temperatures. In order for it to correspond to an actual mechanism we should have to assume that the temperature coefficient of the rate was determined by some unimolecular process with an energy of activation ΔE , and either to neglect the inhibiting effect of oxygen or to assume this inhibiting effect to be determined solely by the total pressure, since this was not varied in our experiments. The mechanism would also have to include steps, perhaps of a chain-like nature, to make the total reaction second order with respect to ozone.

Case B differs from the above in assuming that the rate is to be taken

as inversely proportional to the concentration of oxygen, C_{O_2} . Its interest lies in the fact that Warburg's experiments were made at constant concentration of oxygen, and hence Case B furnishes the most natural value of ΔE to compare with that obtained by Warburg.

Case C would correspond to a mechanism in which the rate-determining step was bimolecular, and the overall rate determined by the total pressure.

Case D corresponds to a mechanism in which the rate-determining step is bimolecular and the overall rate is inversely proportional to the concentration of oxygen, C_{O_2} . This is a particularly interesting case since, as we shall see, the definite mechanism proposed by Jahn fulfils these conditions.

Fig. 3.

These four cases by no means exhaust the possible assumptions as to mechanism. Thus, for example, the inhibiting effect of oxygen might be taken proportional to the number of collisions made between oxygen molecules and some molecular form present during the decomposition rather than to the pressure or concentration. Nevertheless, the four cases show that different assumptions probably will not lead to greatly different values for ΔE .

Let us now turn to a more specific consideration of Case A which gives a simple empirical formula for the rates found, and Case D which corresponds to the Jahn mechanism.

8. Empirical Equation for Rate of Decomposition of Ozone at 1 Atm. Total Pressure

The values of ΔE and k in Expression A were actually obtained by plotting $\log k_2$ against $1/T$ and determining the slope and intercept of the line. The plot of the data given in Table II is shown in Fig. 3. It will

be noticed that the points do fall practically on a straight line, indicating that ΔE may be taken as a constant over the range of temperatures employed.

As a result of the plot we obtain as an expression for the specific second-order rate of decomposition of dilute ozonized oxygen at approximately one atmosphere pressure

$$k_2 = 2.04 \times 10^{10} e^{-30,900/RT} \quad (12)$$

This may be regarded as a simple empirical expression for the rate of decomposition of ozone at 1 atm. pressure. At 100° it gives a value of the specific rate of 1.55×10^2 cc. moles $^{-1}$ sec. $^{-1}$. This falls well within the range of values given in the first article of this series for ozone at 100° .

9. The Jahn Mechanism

To explain the inhibiting effect of oxygen and the second-order character of ozone decomposition, Jahn¹⁰ assumed the following intermediate reactions as expressing the mechanism of the overall change.

In accordance with the first of these reactions, we should have for the concentration of monatomic oxygen

$$C_{\text{O}} = K C_{\text{O}_3} / C_{\text{O}_2} \quad (13)$$

where K is the equilibrium constant for the reaction, and hence, in accordance with the second reaction, we could write for the overall rate

$$-dC_{\text{O}_3}/dt = k'T^{\frac{1}{2}} C_{\text{O}_3} K C_{\text{O}_3} / C_{\text{O}_2} = k'KT^{\frac{1}{2}} C_{\text{O}_3}^2 / C_{\text{O}_2} \quad (14)$$

where k' is a constant independent of temperature, and the number of collisions between ozone molecules and oxygen atoms is taken proportional to the square root of the absolute temperature. The mechanism evidently accounts both for the inhibiting effect of oxygen and the second-order character with respect to ozone.

To obtain the effect of temperature on the overall rate, we may now use the van't Hoff expression for the change in equilibrium constant K with the temperature

$$d \log K / dT = \Delta E / RT^2 \quad (15)$$

and by integrating on the assumption that ΔE is constant, and substituting in Equation 14 obtain the result

$$-dC_{\text{O}_3}/dt = kT^{\frac{1}{2}} e^{-\Delta E/RT} C_{\text{O}_3}^2 / C_{\text{O}_2}$$

or

$$k_2 = (k/C_{\text{O}_2}) T^{\frac{1}{2}} e^{-\Delta E/RT} \quad (16)$$

where k is a new constant independent of the temperature and ΔE is evidently the heat absorbed when Reaction E takes place at constant volume.

¹⁰ Jahn, *Z. anorg. Chem.*, **48**, 260 (1905).

It will be noted that Equation 16 agrees with Case D considered above. To determine the values of the constants occurring in Equation 16, we have plotted in Fig. 4 the value of $(\log k - \frac{1}{2} \log T + \log C_{O_2})$ against $1/T$ and thus obtained the numerical equation

$$k_2 = (5.89 \times 10^{13}/C_{O_2}) T^{\frac{1}{2}} e^{-29,600/RT} \quad (17)$$

As will be seen from Fig. 4, the experimental values fall well on a straight line, and in passing it may be remarked that this was also true for the plots corresponding to Cases B and C, which it did not seem worth while to reproduce here. It should also be remarked that if we regard Equation 17 as an empirical expression of the rate of ozone decomposition, it would presumably take reasonable care of the inhibiting effect of oxygen, which is not done by Equation 12.

Fig. 4.

10. Energy of Activation on Basis of Jahn Mechanism

Since the Jahn mechanism furnishes us with a definite interpretation of the numerical quantities occurring in Equation 17, we now have the possibility of testing this mechanism by investigating the reasonableness of these quantities.

On the basis of the Jahn mechanism the energy of activation, 29,600 cal., should be the heat absorbed at constant volume by the reaction $O_3 = O_2 + O$, giving us the thermochemical equation $O_3 = O_2 + O - 29,600$ cal. Neglecting the small effect of temperature on heats of reaction we may now combine this with the known heat of decomposition of ozone¹¹ at constant volume and room temperature as given by the equation $2O_3 = 3O_2 + 69,000$ cal., and obtain for the heat of dissociation of

¹¹ See the critical analysis of Moeller, "Das Ozon," Vieweg, Braunschweig, 1921, p. 34.

oxygen at constant volume, $O_2 = 20 - 128,200$ cal., which falls within the probable limits for this reaction.¹²

Hence we must conclude that the Jahn mechanism gives a reasonable value for the heat of dissociation of ozone into diatomic and monatomic oxygen and may use the value 29,600 cal. for our further interpretation.

11. Number of Collisions on Basis of Jahn Mechanism

Turning now to the other numerical factor, namely, 5.89×10^{13} , occurring in Equation 17, it is evident on the basis of the Jahn mechanism that this must be related to the number of collisions between ozone molecules and oxygen atoms. Indeed, as a necessary requirement, it is evident that we could calculate the maximum possible value of this constant by assuming reaction at every collision between an ozone molecule and an oxygen atom. We must now investigate this point.

To do so we shall content ourselves with a comparison of the number of collisions and number of reactions occurring in 5% ozonized oxygen at one atmosphere and 100°. To make this comparison we shall first have to calculate by thermodynamic methods the amount of monatomic oxygen which would be present in 5% ozone at 100°, and then use kinetic theory methods to calculate the number of collisions between monatomic oxygen and ozone.

a. Thermodynamic Calculation of Partial Pressure of Monatomic Oxygen.—To calculate the partial pressure of monatomic oxygen in equilibrium with ozone and molecular oxygen, we must know the heat change ΔH and entropy change ΔS accompanying the reaction $O_3 = O_2 + O$. On the basis of the Jahn mechanism, as we saw above, the energy change accompanying this reaction would be 29,600 cal., and hence the heat change at constant pressure and 100° would be

$$\Delta H_{373} = \Delta E + RT = 29,600 + RT = 30,300 \text{ cal.} \quad (18)$$

To calculate the entropy change accompanying the reaction is more involved. We have, however, at room temperature for the reaction $O_3 = \frac{3}{2}O_2$, the well substantiated value, $\Delta H_{298} = -34,200$ cal., and taking the specific heats of ozone and oxygen as given by the equations¹³

$$O_3, C_p = 7.0 + 0.0071 T - 0.00000186 T^2 \quad (19)$$

and

$$O_2, C_p = 6.50 + 0.0010 T \quad (20)$$

obtain at 0° to the nearest hundred calories the same value

$$\Delta H_{273} = -34,200 \text{ cal.} \quad (21)$$

For the free-energy change at 0°, however, we have the value obtained by Jahn,¹⁴

¹² See Wulf, *THIS JOURNAL*, **47**, 1944 (1925); *Lockrow, Astrophys. J.*, **43**, 205 (1926). See also, however, Hogness and Lunn, *Phys. Rev.*, **27**, 732 (1926). Birge and Sponer, *ibid.*, **28**, 259 (1926).

¹³ Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., New York, 1923, pp. 80, 475.

¹⁴ Jahn, *Z. anorg. Chem.*, **60**, 332 (1908). See also Ref. 11, p. 57, which also takes this value.

$$\Delta F_{273} = -30,000 \text{ cal.} \quad (22)$$

which Jahn considers to be correct within an error that cannot be greater than 2000 cal., and may be considerably less.

Combining Equations 21 and 22 we obtain for the entropy change at 0° the value

$$\Delta S_{273} = (\Delta H - \Delta F)/T = -15.39 \text{ cal. deg.}^{-1} \quad (23)$$

and by integrating from 0 to 100° we obtain, with the help of Equations 19 and 20 for the entropy change at 100°, the value

$$\begin{aligned} \Delta S_{373} &= \Delta S_{273} + \int_{273}^{373} \left[\frac{3}{2} C_p(O_2) - C_p(O_3) \right] \frac{dT}{T} \\ &= -15.03 \text{ cal. deg.}^{-1} \end{aligned} \quad (24)$$

for the reaction $O_3 = \frac{3}{2}O_2$.

Furthermore, for the reaction $\frac{1}{2}O_2 = O$, we have at 25° the entropy change¹⁵ $\Delta S_{298} = 9.97$, and taking the specific heat of monatomic oxygen as 5.0, we obtain for this reaction at 100°, by an integration similar to that in Equation 24, $\Delta S_{373} = +10.33$ cal. deg.⁻¹.

We may now add the values of the entropy changes at 100° for the reactions $O_3 = \frac{3}{2}O_2$ and $\frac{1}{2}O_2 = O$, and obtain for the reaction $O_3 = O_2 + O$, the value $\Delta S_{373} = -4.70$ cal. deg.⁻¹.

Referring back to Equation 18 we may then write for the free-energy change and equilibrium constant for this reaction at 100°

$$-RT \log K_p = \Delta F_{373} = \Delta H_{373} - T \Delta S_{373} = 32,100 \text{ cal.} \quad (25)$$

Solving for the equilibrium constant we obtain

$$K_p = p_{O_2} p_O / p_{O_3} = 1.5 \times 10^{-19} \quad (26)$$

where the partial pressures are in atmospheres. For 5% ozone we obtain for the partial pressure of monatomic oxygen at 100° and 1 atm total pressure

$$p_O = (0.05/0.95) K_p = 7.9 \times 10^{-21} \text{ atm.} \quad (27)$$

This partial pressure corresponds to a very small concentration of monatomic oxygen, of the order, indeed, of considerably less than a molecule per cubic centimeter. Nevertheless, we need have no hesitation on this score in taking the figure as giving the true time average corresponding to the monatomic oxygen present, and using it for calculating the number of collisions between monatomic oxygen and ozone.

b. Calculation of Number of Collisions between Monatomic Oxygen and Ozone.—

The number of collisions between ozone molecules and oxygen atoms per cubic centimeter per second may now be calculated from the kinetic theory expression

$$Z = 1.679 \times 10^{32} C_1 C_2 \sigma_{12}^2 T^{\frac{1}{2}} \sqrt{(M_1 + M_2)/M_1 M_2} \quad (28)$$

where σ_{12} is the sum of the radii of the two different kinds of molecules, and C_1 and C_2 are their concentrations in moles per cubic centimeter. For σ_{12} , which is the sum of the radii of an ozone molecule and an oxygen atom, we shall use the value 3×10^{-8} cm., which is practically the same as Chapman's¹⁶ value 2.93×10^{-8} for the sum of the radii of two oxygen molecules.

Substituting in Equation 28 we obtain

$$\begin{aligned} &1.679 \times 10^{32} \frac{0.05}{82.07 \times 373} \frac{7.9 \times 10^{-21}}{82.07 \times 373} (3 \times 10^{-8})^2 (373)^{\frac{1}{2}} \sqrt{\frac{48 + 16}{48 \times 16}} \\ &= 3.6 \times 10^7 \text{ collisions per cc. per sec.} \end{aligned} \quad (29)$$

Comparison of Number of Collisions and Number of Reactions.—We may now

¹⁵ Ref. 13, p. 464.

¹⁶ Chapman, *Phil. Trans. Roy. Soc.*, **216A**, 347 (1916).

compare this figure with the number of reactions occurring under the same conditions between ozone molecules and oxygen atoms which will be given by the expression

$$Z_{\text{React.}} = \frac{1}{2} k_2 C_{\text{O}_3}^2 N \quad (30)$$

where k_2 is the specific second-order rate at 100° , N is Avogadro's number, and the factor $1/2$ enters because in all, two molecules of ozone are used for each such reaction. Taking the specific rate k_2 at 100° as having the value 1.5×10^2 cc. moles $^{-1}$ sec. $^{-1}$ and substituting in Equation 30 we then obtain

$$\begin{aligned} Z_{\text{React.}} &= \frac{1}{2} \times 1.5 \times 10^2 \times (0.05/82.07 \times 373)^2 \times 6.06 \times 10^{23} \\ &= 1.2 \times 10^{14} \text{ reactions per cc. per sec.} \end{aligned} \quad (31)$$

Comparing Equations 29 and 31, we thus see that the number of collisions would be too small by a factor of more than 10^8 to permit us to account for the decomposition of ozone on the basis of the Jahn mechanism.

To obtain a large enough number of collisions to make the Jahn mechanism possible we should have to assume that reaction between ozone and monatomic oxygen could be induced by an approach of the two molecules to a distance of 5.5×10^{-8} cm., or to assume that the free-energy value in Equation 25 is in error by +11,100 cal.

12. Summary

The temperature coefficient of the thermal decomposition of ozonized oxygen has been measured at one atmosphere's pressure using five temperatures in the range 148 to 179° .

The rate of decomposition may be expressed as a function of the temperature at *one atmosphere* pressure by the empirical equation $-dC/dt = 2.04 \times 10^{20} e^{-30,900/RT} C^2$.

The rate under the same conditions may also be expressed by the equation $-dC/dt = (5.89 \times 10^{13}/C_{\text{O}_3}) T^{1/2} e^{-29,600/RT} C^2$, and this equation will also give reasonable values at total pressures other than one atmosphere.

It has been shown by calculation that the Jahn mechanism of ozone decomposition would require more collisions between ozone molecules and oxygen atoms than could actually occur and hence cannot be regarded as tenable, at least in its original simple form.

A NEW EQUATION OF STATE FOR FLUIDS.

I. APPLICATION TO GASEOUS ETHYL ETHER AND CARBON DIOXIDE¹

BY JAMES A. BEATTIE AND OSCAR C. BRIDGEMAN²

RECEIVED APRIL 11, 1927

PUBLISHED JULY 5, 1927

The consideration of certain thermodynamic properties of fluids has led the authors to formulate jointly an equation of state which appears to reproduce accurately the pressure-volume-temperature data.

It is believed that this equation has to a unique degree the following desirable qualities. (a) The numerical values of the constants can be determined easily and uniquely from the pressure-volume-temperature data, and with one exception can be obtained as the intercepts or slopes of straight lines by suitable treatment of the data. (b) The equation is readily amenable to mathematical manipulation since it is completely algebraic. Hence, most of the usual thermodynamic relations can be integrated in terms of elementary functions as, for example, $p dv$ (and therefore $v dp$) at constant temperature. (c) The equation fits the data over a wide range of pressures and temperatures, reproducing the trends as well as the actual pressures. (d) The volume and temperature functions, A , B and ϵ can be expanded further, *if necessary*, without alteration of the general form of the equation. This extension has not as yet been found necessary in the applications which have been made by the authors to gases even up to pressures of 300 atmospheres.

The proposed equation has the following form

$$p = \frac{RT(1 - \epsilon)}{v^2} (v + B) - \frac{A}{v^2}$$

where $A = A_0(1 - a/v)$, $B = B_0(1 - b/v)$ and $\epsilon = c/vT^2$. This relation is being tested on all of the available data on fluids, and this extensive application, together with a theoretical basis for the equation and the detailed method for obtaining the numerical values of the constants, will be given later.

In the present article, the equation is applied to the data on gaseous ethyl ether³ and carbon dioxide,⁴ and the numerical values of the constants for these substances are given in Table I. The units of pressure, volume and temperature are the atmosphere, cc. per gram, and degrees absolute where $T^\circ = t^\circ + 273.13$.

Summary

There is presented a new equation of state which has to a unique extent the desirable features of (a) easy and accurate evaluation of the constants from pressure-volume-temperature data, (b) ease of mathematical manipulation including the integrability of vdp at constant temperature in terms of elementary functions, (c) accurate representation of the data and their trends, and (d) flexibility, in that without alteration of the general form of the equation more terms can be added, if necessary.

The equation, which contains five constants and the gas constant, reproduces the data on gaseous ethyl ether and carbon dioxide at least to a specific volume of 5 cc. per gram, with an average deviation over the whole range of 0.022 and 0.030 atm., respectively (0.07 and 0.08%). An ex-

tensive application to all the available data and a theoretical basis will be given in a later article.

THE SOLID SOLUBILITY OF ANTIMONY IN LEAD AS DETERMINED BY CONDUCTIVITY MEASUREMENTS ON COLD-WORKED ALLOYS

BY EARLE E. SCHUMACHER AND GEORGE M. BOUTON

RECEIVED APRIL 16, 1927

PUBLISHED JULY 5, 1927

Introduction

In 1923, Dean¹ showed the existence of an appreciable solid solubility of antimony in lead at the eutectic temperature. Shortly thereafter Dean, Hudson and Fogler² demonstrated that dispersion hardening takes place in these alloys. They found that a 2.5% antimony alloy, a homogeneous solid solution at 247°, precipitated more than half of its antimony from solution after being maintained at room temperature for a short time. A more detailed study of the solubility conditions, using the conductivity method to follow changes of solubility with temperature, was made by Dean, Zickrick and Nix.³ Unfortunately, at the lower temperatures, they were unable to obtain equilibrium values due to the slow rate of precipitation of the solute.

Recent work indicates that the rate of precipitation of the excess of antimony is greatly accelerated if the alloys are first severely cold-worked. Presumably equilibrium would be reached much more quickly under these conditions. Therefore, it seemed desirable to determine the solid solubility values for antimony in lead on severely cold-worked alloys, hoping thereby to secure more accurate values than those previously obtained.

Photomicrographs Showing the Effect of Cold Work

Several photomicrographs, taken by Mr. F. F. Lucas⁴ of these Laboratories, are given to show the structural effect of cold work in these alloys. A lead-antimony alloy containing 1% of antimony and 99% of lead was cast in the form of a rod, 0.5 inch (1.3 cm.) in diameter. This rod was heated at 230° for one hour to get most of the undissolved antimony into solution. The rod was then divided and one section was severely cold-worked by swaging. Both the worked and unworked sections were maintained at room temperature, 20° for five days and then photomicrographs were taken of each. The specimens photographed

condition before administering the final cold-working. The annealing was followed by a rapid quenching in water, after which the different specimens were severely cold-worked by swaging to approximately 60% of the initial diameter. Samples for chemical analysis were taken just before this final cold-working.

In the case of tests conducted below a temperature of 75°, the wires were immediately placed in a bakelite rack capable of holding 15 specimens. This rack was provided with heavy copper current terminal leads to which the ends of the wires were fastened. The voltage contacts were made of spring brass, sharpened to a knife edge to provide a good contact. When the rack was placed in the thermostat the proper voltage and current connections were made and the test was started. As the test progressed, resistance measurements were made at regular intervals. When the resistance of the wires remained constant for a period of from 200 to 300 hours, equilibrium was considered to have been reached. The wires were then removed from the thermostat and cut off at the knife marks made by the voltage contacts. Their length and weight were accurately determined and their conductivities calculated.

Above 75°, a similar procedure was used except that here the wires had to be protected from direct contact with the oil that filled the thermostat. This was found to be necessary as preliminary tests with several types of oil revealed a development of acidity at temperatures above 75°, which was sufficient to cause corrosion of the test wires. Satisfactory protection was secured by sealing the wires in glass tubes within which the current and voltage contacts were made.

Data typical of those obtained in these measurements are given in Tables I-III. Table I shows the increase in conductivity with time, of some of the wires that were maintained at 25°, and indicates that the conductivity becomes essentially constant before the completion of the test. The data given in Table II were used to prepare the conductivity

curves at various temperatures. Table III gives the determined values for the solid solubility of antimony in lead at the five different temperatures employed in these experiments.

Fig. 4.—Conductivity of lead-antimony alloys at 25°.

Discussion

Since it is evident from the conductivity-time curves, Fig. 9, that at the end of the test the samples were changing very slowly, if at all, we

may assume that the data shown in the conductivity-composition curves, Figs. 4-8, correspond to equilibrium conditions. This assumption is

Fig. 5.—Conductivity of lead-antimony alloys at 40°.

also supported by the photomicrographic evidence presented in a preceding paragraph, which showed that shortly after severe cold-working,

Fig. 6.—Conductivity of lead-antimony alloys at 70°.

samples possess a distribution of antimony similar to that found after prolonged aging in service. These curves accordingly reveal the limiting

values of solid solubility at the respective temperatures. According to the general theory relating conductivity with constitution, alloys lying

Fig. 7.—Conductivity of lead-antimony alloys at 100°.

within the range of solid solubility should show a rapidly decreasing conductivity with increasing antimony content. Beyond the range of solid

Fig. 8.—Conductivity of lead-antimony alloys at 146°.

solubility the conductivity should change at a much slower rate with increasing antimony content. There should, therefore, be a definite

The Revised Constitutional Diagram for the Lead End of the System Lead-Antimony

Since the liquidus³ and solidus lines⁷ at the lead end of the system lead-antimony have already been accurately determined and we have now contributed precise data defining the change of solid solubility with temperature, it is possible to construct a revised diagram for the lead end of this system. Such a diagram is shown in Fig. 10.⁸

Fig. 10.—Partial equilibrium diagram of the system lead-antimony.

Summary and Conclusions

The solid solubility of antimony in lead has been determined for five different temperatures. The solubility changes from 2.45% at 247°, the eutectic temperature, to about 0.25% at 25°, room temperature. Cold work applied to lead-antimony alloys has been shown to decrease materially the time required to reduce the supersaturation of antimony in lead, and thus permits equilibrium values of the solubility to be more readily obtained. A revised constitutional diagram is given for the lead end of the system lead-antimony.

NEW YORK, N. Y.

³ Schumacher and Nix, Preprint No. 1636 E, *Am. Inst. Mining Met. Eng.*, February, 1927.

⁸ Two points on the liquidus and one on the solidus line were determined during the course of this investigation in order to fix more precisely the location of these lines. The points on the liquidus were determined from cooling-curve data; the point on the solidus was determined by the quenching-test procedure developed by Heycock and Neville.

THE DIELECTRIC CONSTANTS OF BINARY MIXTURES. II. THE ELECTRIC MOMENTS OF CERTAIN ORGANIC MOLECULES IN BENZENE SOLUTION

BY JOHN WARREN WILLIAMS AND IGNACE J. KRCHMA

RECEIVED APRIL 19, 1927

PUBLISHED JULY 5, 1927

Theoretical Part

In the study of the dielectric constants of binary mixtures it has been the custom of most investigators to study the properties of the solutions from curves in which the dielectric constants of the mixtures have been plotted against the mole fractions of the constituents.¹ Following this custom, the results of the first paper of this series² were expressed in that manner. The application of the concept of molar polarization introduced by Debye,³ has marked a distinct advance in the mathematical treatment of the properties of these binary mixtures, particularly in the case where one of the liquids, which may be termed the solvent, is known to have no electric moment. The reasons why this method of treatment is more desirable in the case of these mixtures have recently been discussed in detail by Ebert⁴ and by Debye.⁵

The basis of this method of treatment is found in the familiar Clausius-Mosotti law, $P = [(\epsilon - 1)/(\epsilon + 2)](M/d) = (4\pi/3)N\alpha$, where P is the molar polarization, ϵ the dielectric constant, M the molecular weight, d the density; N Avogadro's number = 6.06×10^{23} and α the molecular polarizability.

The molar polarization, P , has been shown⁵ to be a linear function of the reciprocal of the absolute temperature, so that the equation may be written in the form $P = [(\epsilon - 1)/(\epsilon + 2)](M/d) = (4\pi/3)N[(\mu^2/3kT) + \alpha] = (B/T) + A$, where $B = (4\pi/3)N(\mu^2/3k) =$ effect of orientation of molecules in the field, and $A = (4\pi/3)N\alpha =$ effect due to deformation of molecules. The quantity μ in the above equations is a direct measure of the electric moment of the molecules.

Application to Binary Mixtures.—The molar polarization, $P_{1,2}$, of a binary mixture is given by the expression⁵

$$P_{1,2} = [(\epsilon - 1)/(\epsilon + 2)](f_1M_1 + f_2M_2)/d = f_1P_1 + f_2P_2$$

where f_1 and f_2 = mole fractions of Components 1 and 2; M_1 and M_2 = molecular weights of Components 1 and 2; P_1 and P_2 = molar polarizations of Components 1 and 2; $P_1 = (4\pi/3)N\alpha_1$, and $P_2 = (4\pi/3)N\alpha_2$.

Measurements of the dielectric constants of binary systems in which the first component, the solvent, is known to have no electric moment, permit a calculation of the molar polarization, and therefore of the electric moment of the second component. Liquids such as carbon tetrachloride, carbon disulfide, pentane, hexane and benzene should serve as solvents of this type. The purpose of this paper is to present the results of calculations of the electric moments of certain organic molecules from measurements of the dielectric constants of their solutions in benzene, calculated with the help of the equations given above, and to point out certain limitations to the general application of this method of treatment.

Method

The method used for the determination of the dielectric constants of the binary mixtures was explained in detail in the first paper of this series² and will not be described here. It might be stated, however, that each of two dielectric cells similar to the one described in the previous paper was used for each measurement wherever possible. Since these two cells were of widely different capacitances, the fact that measurements on solutions of the same composition gave the same result within the limit of experimental error would vouch for their accuracy.

The refractive indices of the pure liquids and of the solutions were measured by means of a Pulfrich refractometer immediately after the dielectric-constant determination. Except when noted to the contrary, their densities were determined at 25° by means of an Ostwald-Sprengel pycnometer, taking the usual precautions for temperature regulation.

Purification of Materials

An outline of the method of purification of each substance used is given below. The physical constants of each, density, and refractive index are included as part of Table I, under Experimental Results.

Benzene.—The benzene, obtained from the Eastman Kodak Company, was shaken with concd. sulfuric acid, washed with dil. sodium hydroxide solution and with distilled water. It was frozen out twice and fractionated, and showed no blackening with mercury. The drying agent used was phosphorus pentoxide. The liquid gave practically the same physical constants that are given by Richards and Shipley,⁴ b. p., 80.10–80.15°.

Toluene.—This material was obtained from the Mallinckrodt Chemical Works. It was shaken with concd. sulfuric acid, washed with dil. sodium hydroxide and distilled water. After standing over mercury for a week it was dried with phosphorus pentoxide and fractionated; b. p., 110.60–110.80°.

***o*-Xylene.**—This liquid was obtained from Kahlbaum. It was shaken with concd.

⁴ Richards and Shipley, *THIS JOURNAL*, 41, 2002 (1919).

sulfuric acid, treated with dil. sodium hydroxide solution and washed with water. It was dried with phosphorus pentoxide and fractionated; b. p., 142.3–142.5°.

p-Xylene.—The xylene, also obtained from Kahlbaum, was subjected to a treatment similar to that of the *o*-xylene and fractionated; b. p., 138.3–138.4°.

Chloroform.—The material was obtained from the Eastman Kodak Company. It was treated with concd. sulfuric acid to remove alcohol and washed with dil. sodium hydroxide and water. It was dried over fused calcium chloride. After further drying with anhydrous copper sulfate, it was fractionally distilled; b. p., 61.10–61.20°.

Carbon Tetrachloride.—The preparation (obtained from Merck and Company) was refluxed over mercury and washed with concd. sulfuric acid to remove sulfides. It was then washed with dil. sodium hydroxide solution and water, dried over fused calcium chloride and fractionated; b. p., 76.45–76.52°.

Chlorobenzene.—This material was obtained from the Eastman Kodak Company. It was carefully dried and fractionated; b. p., 131.80–131.90°.

Ethyl Ether.—This material was obtained from the Mallinckrodt Chemical Company. It was treated with concd. sulfuric acid, washed, dried with calcium chloride and finally with sodium, and fractionated; b. p., 34.5–34.7°.

Phenol.—The phenol, obtained from Merck and Company, under the label "U. S. P. IX—'C P.'—Loose Crystals," was simply melted and fractionated; b. p., 181.3–181.5°.

Experimental Results

The results of the experimental determinations are summarized in Table I. The columns of this table give, from left to right: the mole fraction of the benzene which was used as the solvent, MFC_6H_6 ; the refractive index of the solution, n_D^{25} ; the density of the solution, d_4^{25} ; the observed dielectric constant, ϵ ; the molar polarization of the solution, $P_{1,2} = [(\epsilon - 1)/(\epsilon + 2)](f_1M_1 + f_2M_2)/d = f_1P_1 + f_2P_2$; and the molar

¹ Data of Mr. R. J. Allgeier, as yet unpublished. Another article of this series, on the dielectric constants of benzene solutions of certain solid substances, by Mr. Allgeier and the senior author of this paper, will be published in the near future.

^b The dielectric-constant and refractive-index data for these systems were presented in the previous paper of this series.²

^c Density data, d_4^{25} , taken from Linebarger [*J. Am. Chem. J.*, **18**, 429 (1896)] and calculated to d_4^{25} .

polarization of the second component, $P_2 = (P_{1,2} - f_1 P_1)/f_2$, and obtained by graphical methods.

The dielectric constants of the pure liquids and of the solutions were measured at 25°, using a frequency of the order 10^6 cycles per second.

Discussion of Results

Experiments in binary liquid mixtures in which one of the components has no electric moment give results from which certain calculations concerning the electric moment of the other component can be made. The assumption is made in this method of treatment that the polarization due to the non-polar solvent (in this article, benzene) is always directly proportional to its mole fraction in solution. Although for such considerations benzene would appear to be an ideal solvent, and indeed has already been used as such by Lange,⁷ this assumption may not be entirely borne out by experimental data on certain physical properties of the liquids. For example, benzene seems to show a somewhat abnormal behavior in solution with butane.⁸ It shows evidence of a slight association in its specific heat-temperature curve.⁹ It gives a slightly abnormal solution with carbon tetrachloride (a liquid whose moment is without doubt smaller than that of benzene) on the basis of specific-heat relations,¹⁰ etc. It would seem that the assumption, while probably true in an infinitely dilute solution of the second component, fails to take into account what might be termed the chemistry of solution, that is, the changes which take place upon the addition of any finite quantity of the second component. These changes taking place upon solution have been discussed in a number of places,^{10,11} and will not be presented here.

However, for the purpose of discussion, the above assumption will be made in the treatment of the binary mixtures whose constants were presented in Table I. It is convenient to divide the systems into two groups. Group 1 combines the systems in which the molar polarization of the second component, P_2 , is constant throughout the whole range of concentration. These are benzene containing (1) *p*-xylene, (2) *o*-xylene, (3) phenol, (4) carbon tetrachloride, (5) ethyl ether. In Group 2, P_2 is not a constant: benzene containing (6) toluene, (7) chlorobenzene, (8) chloroform.

In Group 1 are found what might be termed ideal solutions, since the molar polarization of the second component is exactly proportional to its mole fraction in the solution. As a typical example of a binary mixture of this type, curves showing the molar polarizations of the second component, and of the solution of benzene and ethyl ether, plotted against the mole fraction of benzene, are presented in Fig. 1. Curve I gives the product of f_1 by P_1 ; Curve II gives the molar polarization of the solution calculated from the relation $P_{1,2} = [(\epsilon - 1)/(\epsilon + 2)](f_1M_1 + f_2M_2)/d$,

¹¹ Hildebrand. "Solubility." Chemical Catalog Co., New York, 1924.

and Curve III gives the molar polarization of ether, P_2 , obtained from Curves I and II. It will be evident from Curve III that P_2 is a constant. This may be interpreted to show that the electric moment of an ether molecule does not change, whether it be completely surrounded by benzene molecules (infinitely dilute solution in benzene), or by both benzene and ether molecules, or by other ether molecules.

Fig. 1.—Benzene-ethyl ether. Ordinates: Curve I, $f_1 P_1$; Curve II, $P_{1,2}$; Curve III, P_2 .

It should be emphasized that these solutions are ideal only with respect to their molar polarizations in solution. Vapor pressures, specific volumes and specific heats of these solutions may show considerable deviations from ideality, yet their dielectric properties may be normal. The liquids chosen, *o*-xylene, *p*-xylene, phenol, carbon tetrachloride and ethyl ether, represent four different types of organic compounds, only one of which is at all chemically similar to the solvent, benzene.

The binary mixtures in Group 2 give values of $P_{1,2}$ which, when plotted against the mole fraction of the solvent, do not fall on a straight line. Since the molar polarization of the solvent is assumed to be directly proportional to its mole fraction in the solution, it is evident that P_2 will no longer be a constant. These quantities are obtained in a manner exactly analogous to that of the solutions of Group 1.

Fig. 2.—Benzene-toluene.

The type of curve obtained for these systems is illustrated by Figs. 2 and 3, in which the molar polarization of benzene-toluene solutions, and the molar polarization of the toluene in solution, respectively, are plotted against the mole fraction of benzene.

In the case of solutions of this group the value of P_2 is obtained by taking a tangent to the $P_{1,2}$ curve at the point where the mole fraction of the reference liquid is unity, and prolonging it until it cuts the axis where the mole fraction of the other component is unity, as shown in Fig. 2. For the intermediate concentrations, the values of P_2 are obtained directly from those of f_2P_2 , since $P_{1,2} = f_1P_1 + f_2P_2$, and $P_{1,2}$ and f_1P_1 are known.

The explanation of the form of curve obtained for systems of this group has been given by Debye.⁵ It is at present a qualitative explanation,

comparable in many respects to the type of explanation given to account for the deviations from ideality of the physical properties of binary mixtures.^{10,11}

Calculation of the Electric Moments of the Molecules

The electric moment of a molecule surrounded by the inert molecules of a non-polar solvent may be calculated in the following manner. The molar polarization of the dissolved substance, P_2 , contains two terms, one a polarization due to orientation, P'_2 , the other a polarization due to deformation, P''_2 , so that the equation $P_2 = P'_2 + P''_2$ may be written. Rearranging, $P'_2 = P_2 - P''_2$. The term P_2 has been calculated for each

Fig. 3. —Benzene-toluene.

solute in benzene, and included in Table I. For all the calculations of this section the value of P_2 is taken as that value determined in the infinitely dilute solution in benzene, given in the table for 100 mole fraction of benzene. This molar polarization is due, therefore, to a single solute molecule completely surrounded by benzene molecules. The term P''_2 may be approximated by means of the familiar Lorenz-Lorentz¹² formula, $P''_2 = [(N_0^2 - 1)/(N_0^2 + 2)](M/d)$, where N_0 is the refractive index of the substance extrapolated to zero frequency. This extrapolation, of course, can only be made when there is no interfering infra-red absorption. Although it cannot be considered as exact because experimental measurements of the relation between the refractive index and the frequency have not as yet been made in the longer infra-red regions, it gives a result of sufficient accuracy so that the deformation term may be calculated.

¹² Lorentz, *Wied. Ann.*, 9, 641 (1880).

The method of calculation of the electric moment of a molecule is illustrated by a sample computation for the ethyl ether molecule. $P'_2 = P_2 - P''_2 = 54.5 - 23 = 31.5$ cc. $P'_2 = (4\pi/3)N(\mu^2/3kT) = 31.5$, where N is Avogadro's number, μ the electric moment of the molecule, k the Boltzmann constant $= 1.37 \times 10^{-16}$ and T is the absolute temperature, 298° . Making the substitutions, $\mu = 1.22 \times 10^{-18}$.

The electric moments of the several solute molecules, computed in the above manner, are presented in Table II.

TABLE II
ELECTRIC MOMENTS OF SOLUTE MOLECULES AT 25°

Molecule	P''_2 , cc.	P'_2 , cc.	$\mu \times 10^{18}$
Ethyl ether	23.0	31.5	1.22
Carbon tetrachloride	28.3	0	0.00
<i>p</i> -Xylene	35.5	1.0	.06
<i>o</i> -Xylene	35.0	5.8	.52
Chloroform	21.3	26.2	1.10
Toluene	30.3	5.9	0.52
Chlorobenzene	30.2	51.8	1.55
Phenol	27.7	61.3	1.70

Discussion of Table of Electric Moments

Two of the molecules studied, carbon tetrachloride and *p*-xylene, are symmetrical in structure, in which case the electric moment should be zero. The values found indicate that if these molecules have any moment at all it must be of a very small magnitude. Indeed it could hardly be expected that the values of P''_2 might not show an error of ± 1 cc. so that within the limits of the accuracy of the method used, the electric moments of these molecules may be considered to be zero. Since the dielectric constants of benzene and *p*-xylene are so nearly alike, it is difficult to calculate an exact moment for the latter substance in benzene solution.

The electric moments of the toluene and of the *o*-xylene molecule are perhaps somewhat larger than might have been predicted. Smyth¹³ has calculated the electric moments of the toluene and the various xylene molecules "from the indices of refraction at two different wave lengths, the density of the substance under the conditions under which these indices were measured, the dielectric constant at one temperature, the density at this temperature, the value of the temperature itself, the molecular diameter and certain universal constants." These calculated moments are not in particularly good agreement with the experimental ones here presented. The values calculated by Smyth have been criticized by Sanger¹⁴ and will not be discussed here. It is a fact^{2,10} that when small amounts of toluene are dissolved in benzene at 25° , the solution

¹³ Smyth, *THIS JOURNAL*, **46**, 2151 (1924).

¹⁴ Sanger, *Physik. Z.*, **27**, 165 (1926).

behaves abnormally. Since the tangent to the molar polarization curve for an infinitely dilute solution of toluene in benzene gives the quantity P_2 , it must be expected that the term P'_2 will be comparatively large, thereby resulting in a large moment. It is interesting to note that in the case of the symmetrical xylene the electric moment is practically zero, while in the case of the unsymmetrical xylene the electric moment has a significant value.

The values obtained for ethyl ether and chloroform may be compared with others found in the literature. Lange⁷ has determined the electric moment of ethyl ether, obtaining the identical result tabulated above. This investigator determined the dielectric constants of solutions of benzene and ether, using a modified Nernst bridge method. Sanger¹⁵ has recently determined the moment of chloroform in the vapor state with the result $\mu = 0.95 \times 10^{-18}$. The value found in benzene solution is only slightly larger.

Kerr¹⁶ determined the dielectric constants of a number of binary mixtures in which benzene was used as a solvent, among them the system benzene-chlorobenzene. Kerr did not calculate the electric moments of the solute molecules, so that the result given above cannot be compared with others as yet. Indeed, it is the opinion of the present authors that these data are of insufficient accuracy for this calculation, because of the manner of preparing the solutions and of the degree of reproducibility of the dielectric-constant data.

The value reported for phenol would seem to be of the right order of magnitude. It cannot be considered to be exact because certain approximations had to be made concerning the properties of a phenol in the liquid state at the temperature of the measurements.

Conclusion

Although the method of treatment of certain binary systems described above was presented by Debye³ a number of years ago, it is only within recent years that investigators, chiefly chemists, have begun to apply it. This paper and several to follow, using other non-polar liquids as solvents, attempt to show the utility of the Clausius-Mosotti law in the calculation of the electric moments of certain molecules dissolved in a non-polar solvent.

The authors take this opportunity to express their thanks to Professor Debye for his kindly interest, advice and encouragement in the interpretation of the experimental data.

Summary

1. The application of the Clausius-Mosotti law to the treatment of dielectric-constant data of certain binary liquid mixtures has been discussed.

¹⁵ Sanger, *Physik Z.*, **27**, 556 (1926)

¹⁶ Kerr, *J. Chem. Soc.*, **128**, 2796 (1926)

2. The dielectric constants of six binary mixtures at 25° have been determined at various concentrations. The systems studied are benzene-*p*-xylene, benzene-*o*-xylene, benzene-ethyl ether, benzene-chloroform, benzene-chlorobenzene and benzene-phenol.

3. The systems have been grouped for discussion according to whether or not the molar polarization of the solute in solution changes with concentration.

4. The electric moments of each of the solute molecules in benzene solution have been calculated. These results have been critically discussed.

NOTE—Since this paper was written there has appeared an article by Smyth and Morgan [THIS JOURNAL, 49, 1030 (1927)] in which the electric moments of certain substituted benzene molecules were calculated from dielectric-constant and density data. Smyth and Morgan have apparently obtained dielectric-constant and density data for but one system reported in this paper, namely, benzene-chlorobenzene. The data used for the calculations for the moment of phenol were taken from a paper by Philip and Haynes [*J. Chem. Soc.*, 87, 998 (1905)]. Since Smyth and Morgan have withheld their dielectric-constant data for a future publication, and since all the dielectric-constant data used by these authors were obtained using bridge methods rather than one of the newer and more accurate electrical resonance methods, the authors of the present paper have decided to submit their paper in its original form.

ADSORPTION FROM SOLUTION BY ASH-FREE ADSORBENT CHARCOAL. IV. THE NON-INVERSION OF SUCROSE BY ADSORBED ACIDS AND ITS SIGNIFICANCE FOR THEORIES OF ADSORPTION AND CATALYSIS¹

By ELROY J. MILLER AND SELMA L. BANDEMER

RECEIVED APRIL 23, 1927

PUBLISHED JULY 5, 1927

Information that will throw light on the properties and behavior of substances in the adsorbed state is much needed for a better understanding of the nature of adsorption, catalysis, and reactions at interfaces. In the present paper are presented the results of a study of the properties of acids when adsorbed on pure ash-free adsorbent charcoals.

In a previous paper² methods were described whereby adsorbed acids can be removed from pure ash-free charcoal and quantitatively estimated. By means of these methods it was demonstrated³ with hydrochloric acid and pure charcoal that a certain amount of adsorbed acid is held so firmly

¹ Published by permission of the Director of the Experiment Station as Journal Article No. 41.

² Miller, THIS JOURNAL, 46, 1150 (1924).

³ Miller, *ibid.*, 47, 1270 (1925).

that it cannot be removed by washing with water alone, either at room temperature or at boiling temperature. Evidence of the tenacity with which adsorbed acids are held by charcoal is also furnished by the fact that acid is hydrolytically adsorbed from a neutral salt, such as potassium chloride, even in the presence of 0.01 *N* potassium hydroxide and that in order to remove the acid quantitatively it is necessary to extract the charcoal several times by boiling with an amount of alkali somewhat in excess of that equivalent to the acid on the charcoal.

These facts seemed to indicate that the adsorption forces were sufficiently strong to affect profoundly the properties of the acid. They also suggest that the adsorption is not simply a concentration of the acid in the water side of the charcoal-water interface. Further evidence on the properties of adsorbed acids was sought by attempting to determine whether or not adsorbed acids are capable of inverting sucrose and, if so, whether the action is catalyzed by the increased concentration of acid and sugar through adsorption. The ash-free adsorbent charcoals prepared as previously described,⁴ because of their purity and high adsorption capacity, are ideal substances for use in such a study. The amounts of adsorbed acid can be controlled accurately and there can be no doubt that the acids are truly adsorbed and not combined with impurities. The fact that known amounts of acids can be added and quantitatively removed and estimated gives further assurance that the conditions are under strict control.

Materials and Methods Used

The charcoals used in this investigation were from three sources—activated sugar charcoal, Norite and blood charcoal. The method of preparation of the sugar charcoal was essentially the same as that previously described.^{4a} The Norite and blood charcoal were purified by the method described in a previous publication.^{4b} All three charcoals were practically ash-free, containing at the most only a few hundredths of a per cent. of ash. They were all ground to pass through a 300-mesh sieve. The usual tests⁵ for the presence of adsorbed acids and alkaline impurities were applied to each lot of charcoal before use, in order to insure the absence of these substances. The sugar used was recrystallized cane sugar practically free from invert sugar. One g. contained less than a milligram of invert sugar and this was corrected for in blank determinations. The sugar solutions were analyzed for total sugar and invert sugar before and after treatment with the charcoal. Two methods were used: the Shaffer-Hartmann⁶ modification of the Benedict method for the determination of the invert sugar, and Willaman and Davison's⁷ modification of the picric acid method for the determination of both total sugars (sucrose, glucose and fructose) and invert sugar remaining in solution after adsorption.

Outline of Procedure

The charcoal (2 g.) was suspended in conductivity water in an Erlenmeyer flask and the system evacuated to remove air and insure thorough wetting. The acid was then added and the suspension allowed to stand with occasional shaking for approximately 16 hours. After this period the charcoal was filtered off with the aid of suction in a Gooch crucible, the filtrate tested for acid, and the charcoal transferred to an Erlenmeyer flask containing 100 cc. of a 5% sugar solution. This suspension was digested with frequent shaking for one and a half hours in a water-bath at 80°. Near the end of the digestion period the charcoal was allowed to settle to the bottom of the flask so that the supernatant solution could be decanted while the temperature was still at 80°. (Since the charcoal suspensions in many cases filtered rather slowly, decantation was necessary in order to keep the suspension from cooling, with the consequent greater adsorption of the solutes at lower temperatures, as would have occurred had the suspension been filtered. Also, by decanting the solution it could be quickly cooled and the inverting action of the acid stopped. While, theoretically, the inversion would go on to some extent in the cold, in practice this action was of negligible magnitude because of the small quantities of acid in the solutions.) The decanted solution was cooled as quickly as possible in running water and then filtered through a disk of filter paper in a Gooch crucible in order to remove the small amount of charcoal that had not settled out. The acid in the filtrate was determined on an aliquot. Since the quantity of acid in the filtrate was usually small, a 50cc. portion was used for titration with 0.02 *N* sodium hydroxide solution. Phenol red was used as indicator. Aliquots of suitable size were taken for use in the methods mentioned above for the determination of total sugar and for invert sugar.

Experimental Part

After a number of preliminary experiments it seemed certain that the only inversion which took place was with the acid and sucrose remaining in solution in equilibrium with adsorbed acids and sugars, for not the slightest trace of invert sugar was ever detected when the charcoal was free from adsorbed acid or when the amount of adsorbed acid was sufficiently small to be adsorbed irreversibly at 80° and was not displaced by the adsorption of sugar at that temperature. It was decided, therefore, to test this point further, using the charcoals with hydrochloric and benzoic acids as representatives, respectively, of groups of acids of low and of high adsorbability. The amount of adsorbed acid held irreversibly adsorbed at 80° depended upon the activity of the charcoal and the adsorbability of the acid. For example, 2 g. of blood charcoal adsorbed irreversibly nearly 10 cc. of 0.02 *N* hydrochloric acid and nearly 50 cc. of the highly adsorbed benzoic acid. When larger quantities of acid were added to the charcoals some acid appeared in solution at 80° in the presence of sugar. In these instances inversion of sugar, of course, always took place. Since relatively large amounts of sugar were also adsorbed, the amount of total sugar (sucrose+invert sugar) remaining in solution at 80° was determined as stated above. The amount of total sugar adsorbed varied with the amount of adsorbed acid on the charcoal. The presence of a large amount of adsorbed acid cut down appreciably the adsorption of the sugar.

It was deemed desirable to determine whether the amount of invert sugar found in the solution after digestion was the same as would be produced by the action of the unadsorbed acid on the unadsorbed sucrose

Fig. 1.—Data for blood charcoal. ○, Hydrochloric acid and invert sugar in solution after digestion with charcoal; □, invert sugar with hydrochloric acid and 3.92% sucrose; ●, benzoic acid and invert sugar in solution after digestion with charcoal; △, invert sugar with benzoic acid and 4.35% sucrose.

found in the solution at 80°. If this were found to be the case it would be additional evidence that adsorbed acids are incapable of inverting sucrose. Since it would involve an unnecessarily large amount of work

Fig. 2.—Data for Norite. ○, Hydrochloric acid and invert sugar in solution after digestion with charcoal; □, invert sugar with hydrochloric acid and 4.40% sucrose; ●, benzoic acid and invert sugar in solution after digestion with charcoal; △, invert sugar with benzoic acid and 4.64% sucrose.

to determine the amount of inversion by the various amounts of sugar and acid found in solution at 80° and since considerable error might be

introduced in titrating a small quantity of acid (0.1–1.0 cc., 0.02 *N*), a slightly different procedure was followed. The average of the amounts of unadsorbed sucrose found in solution in the experiments with varying amounts of a given acid was calculated. The amount of inversion produced at 80° by given amounts of the acid in question on this amount and concentration of sugar was determined, and from these data a curve was constructed from which could be read the amount of invert sugar that would be produced by the action of any quantity of acid within the range of that found in the solutions in contact with the charcoal in the experiments.

The data show conclusively the following facts. (1) Pure charcoal free from adsorbed acids does not invert sucrose. (2) When the acid is irreversibly adsorbed there is no inversion of sucrose at 80°, even though as much as 1 g. of sucrose was adsorbed by 2 g. of charcoal carrying varying quantities of acids. This would seem to imply a very high concentration of sucrose on the carbon. (3) When sufficient amounts of acid were added to the charcoal so that at 80° there was reversible adsorption and displacement of some of the acid by the sugar, there was always inversion. The amount of sugar inverted under these conditions was the same as that inverted by an amount of acid and sugar equivalent to the unadsorbed acid and sugar under the same conditions but in the absence of charcoal. It is certain that the only inversion is that produced by the acid not adsorbed. (4) Large amounts of adsorbed acid and adsorbed sucrose can be held by the charcoal without producing any inversion at 80°.

Results with Acids of Various Types

In order to determine whether the non-inversion of sucrose by adsorbed acid is a general phenomenon, the behavior of a number of acids of various types was investigated. The procedure was practically the same as above. To 2 g. of blood charcoal was added (1) a quantity of acid sufficiently small so that it was completely and irreversibly adsorbed at 80° in the presence of sugar and (2) a quantity of acid large enough so that at 80° in the presence of sugar some acid appeared in solution. The data appear in Table XIII. The results show conclusively that inorganic, aliphatic,

dicarboxylic and aromatic acids, when adsorbed, are incapable of inverting sugar and that inversion takes place only when the adsorbed acids have been displaced from the charcoal.

Results with Salt Solutions and Acid-Salt Mixtures

The data thus far presented show definitely that whatever the mechanism of the adsorption and whatever the condition of the adsorbed acids and sugar on the charcoal, there is no inversion of the sugar by the acid. It has been shown in previous papers^{2,8} that pure ash-free charcoal adsorbs acid hydrolytically from solutions of neutral salts and sets free an equivalent amount of alkali which remains in solution. There is, at the same time, adsorption of some of the solvent, for in the case of the inorganic salts such as potassium chloride, sulfate and nitrate the solution remaining after adsorption is more concentrated with respect to the positive ion than before.³ The inversion or non-inversion of sucrose by the charcoal in salt solutions should yield information regarding the state of the adsorbed acid and adsorbed water. Provided sugar were inverted it would indicate that the acid is free in solution. Non-inversion would show that either or both the acid and sugar and possibly the water, too, are bound in such a manner that they no longer have the properties of ionization and mobility which they possess in ordinary aqueous solution. Since these salt solutions in equilibrium with the adsorbed substances on the charcoal are alkaline, any inversion produced would necessarily have to be attributed to the adsorbed acid on the charcoal or in the film immediately surrounding the charcoal. The procedure in this case was as follows. The charcoal (2 g.) was added to the salt solution or to the acid-salt mixtures and allowed to stand overnight. Sufficient sugar and water were then added to make 100 cc. of a 5% sucrose solution and the

⁸ Bartell and Miller, *THIS JOURNAL*, **45**, 1106 (1923).

suspension was digested at 80° for one and a half hours as usual. The total quantity of adsorbed acid on the charcoal was the sum of the added acid and the acid hydrolytically adsorbed from the salt solution. The latter was, of course, equivalent to the amount of alkali found in the solution at 80°. The data for sugar charcoal and purified blood charcoal with potassium chloride and sodium benzoate are presented in Table XIV. These data show definitely that there was no inversion under these conditions or even when the quantity of adsorbed acid was augmented by the addition of small quantities of acid to the salt solution. Similar results were obtained when other types of salts, such as methylene blue chloride, were used.

Adsorption of Glucose from Solution

Negative catalysis has sometimes been explained on the theory that the products of reaction are adsorbed so strongly by the catalyst that a coating of the reaction products is formed, through which the reactants cannot diffuse, thereby stopping or slowing down the reaction. The possibility that such conditions might be operative in the present work was investigated. The adsorption of glucose alone and in mixtures with sucrose was determined, as well as the displacement of adsorbed glucose by sucrose. The data in Tables XV and XVI show that the presence of sucrose in the usual 5% solution cut down greatly the adsorption of glucose. It is also evident that the glucose, if formed even in minute quantity on the charcoal, would be largely displaced and would appear in solution where it could be detected. When as little as 5 mg. of glucose was adsorbed on 2 g. of charcoal, more than half of it was displaced when the charcoal was suspended in the usual 100 cc. of 5% sucrose solution at 80°. There is evidence that fructose is even less adsorbed than glucose. It is certain, therefore, that strong adsorption of the products of reaction is not the cause of the negative catalysis in this case.

Discussion

The results of this investigation show conclusively that acids when adsorbed on charcoal are incapable of inverting sucrose. The fact that the inversion process is not merely slowed up but completely stopped by adsorption is of importance for certain theories of adsorption and contact catalysis.

It seems certain that in adsorption of acids (and probably other substances) from solutions by charcoal there is not merely a concentration of the acid in solution at the interface nor in a highly concentrated film of solution on the adsorbent and separate from the equilibrium solution as postulated by Ostwald and Izaguirre.⁹ If adsorption of acid and sugar were of this nature, inversion undoubtedly would take place.

The results, likewise, point to a conclusion contrary to that frequently accepted with regard to the adsorption of acids. It is frequently considered that when acids are adsorbed there exists at the interface or around the particles of the adsorbent a higher concentration of hydrogen ions than in the bulk of the solution. The existence of a high concentration of hydrogen ions or indeed of any hydrogen ions on the surface of the charcoal particles carrying adsorbed acids seems absolutely disproved by this work. Since it is fairly certain that the inversion of sucrose by acids is due solely to the hydrogen ion it seems reasonable to conclude that the adsorbed acids on charcoal are in an undissociated state.

The possibility that oriented adsorption of either or both the acid or sucrose molecules might be responsible for the negative catalysis seems precluded, in this case at least, by the fact that the reaction is completely inhibited. If it were merely retarded, orientation, whereby there might arise a tendency to keep the reactive parts of the molecules from coming together, would have to be considered. Furthermore, the orientation of the acids would undoubtedly be with the hydrogen ion away from the charcoal and toward, or in, the water phase for it was shown^{8,10} that adsorption by pure charcoal is an oriented adsorption and that the charcoal attracts the hydrocarbon end of the carboxylic acid molecule. The orientation with the carboxyl group and the hydrogen ion toward the water or solution phase should favor inversion, provided, of course, the sucrose molecules were not adversely oriented. According to the "diffuse" double-layer theory of Gouy,¹¹ the hydrogen ions under these conditions should extend for an appreciable distance into the solution. This should result in inversion. The data in Table XIII show, however, that neither adsorbed inorganic acids nor adsorbed carboxylic acids are able to cause inversion. Thus, considerations of orientation also make it seem rea-

¹¹ Gouy, *J. phys.*, 9, 457 (1910).

sonable to conclude that the adsorbed acid is in an undissociated state.

It is generally considered¹² that charcoal does not catalyze many reactions. There are, however, a number of instances of heterogeneous contact catalysis in which charcoal acts either as a positive or negative catalyst. As illustrations may be cited the work of Firth and Watson¹³ on the catalytic decomposition of hydrogen peroxide and the studies of Kruyt and van Duin¹⁴ on the catalytic effect on the saponification of ethyl acetate, the removal of bromine from α,β -dibromopropionic acid by potassium iodide, and other reactions. The saponification of ethyl acetate was retarded by charcoal while the removal of bromine was accelerated. These authors emphasized the fact that simple adsorption or concentration of the reactants at an interface is not sufficient to catalyze a reaction. They explained the results on the basis of the Langmuir-Harkins theory of oriented adsorption.

Non-inversion of sucrose by adsorbed acids on charcoal is apparently an extreme instance of negative catalysis in which both reactants are adsorbed. As pointed out above, oriented adsorption does not seem to account for the complete inhibition of the reaction. Neither does the theory that the reaction products are so strongly adsorbed that they slow up or stop the reaction seem to offer any possibilities. On the contrary, it appears that the reactants themselves are so strongly adsorbed that they cannot react.

Since the reaction in this instance involves as one of the reactants the hydrogen ion and not the undissociated acid it seems reasonable to conclude that the adsorbed acid on the charcoal is held in the form of undissociated molecules or, possibly, as neutral atoms or groups on the adsorption points of the charcoal lattice. Such an explanation would seem to account satisfactorily for the phenomenon.

Summary

1. Evidence has been submitted to show that adsorbed acids on ash-free charcoals are unable to invert sucrose.
2. It is suggested that adsorbed acids on charcoal are in an undissociated state.
3. Contrary to existing ideas the adsorption of acids does not imply a high concentration of hydrogen ions around the adsorbent.
4. The significance of the non-inversion of sucrose by adsorbed acids for certain theories of adsorption and catalysis has been pointed out.

THE EFFECT OF INORGANIC SALTS ON THE ADSORPTION OF INORGANIC ACIDS AND BASES

BY L. R. PARKS AND P. G. BARTLETT

RECEIVED¹ MAY 4, 1927

PUBLISHED JULY 5, 1927

It is the generally accepted idea that the stability of colloidal dispersions is dependent upon the presence of an electrical charge on the dispersed particle.² This electrical charge is generally conceded to be due to the adsorption of an ion.³ However, the actual mechanism of such adsorption is by no means completely understood. Many investigations have been performed in order to furnish data by means of which some general theory of adsorption could be formulated. Thus far the work done has yielded results which vary widely. Consequently, it has been impossible to formulate any one theory of adsorption which will fit the known facts in all cases. Probably the most important reason for the wide variation in the results published is the use of complex and impure adsorbents. Chemical reactions with impurities would appear as adsorption. Relatively few attempts have been made to purify the adsorbent so that only adsorption would take place.

The investigations on the adsorption of acids and bases by charcoal in the presence of a salt with a common ion, as performed by Michaelis and Rona,⁴ are considered in practically all theoretical discussions pertaining to adsorption. However, Miller's work⁵ has demonstrated that the former investigation is open to criticism. Therefore, for these experiments charcoal was chosen as the adsorbent because it could be prepared in a very pure state.

Some of the experiments of Michaelis and Rona have been repeated, using Merck's blood charcoal as reported by them, as well as a pure form of charcoal.

Preparation and Activation of the Charcoal

Many different methods of purifying charcoal have been published.⁶

Use of commercial charcoals is not satisfactory, since all contain large amounts of impurities. Blood and bone charcoal are known to be of a very complex nature. Even a sample of supposedly pure commercial activated sugar charcoal was found to contain 28% ash. Although the ash from this charcoal was largely soluble in hydrochloric acid, it has been shown that boiling with concentrated acids is inadequate in removing the impurities from the charcoal.⁷ Other suggested methods present similar difficulties. Consequently it was considered necessary to use specially prepared charcoal.

In preparing the charcoal, the best obtainable commercial cane sugar was recrystallized three times from conductivity water. In preparing the conductivity water the same method as that adopted by Harkins was used.⁸ The recrystallized sugar, dried by suction on a Büchner funnel, was then charred at a low temperature in a platinum dish and ignited in order to burn off the adsorbed hydrocarbons.

Another portion of the sugar was charred by treating it with concd. sulfuric acid, and washing until the water showed no acidity when treated with methyl orange.

Freshly charred charcoal is not adsorptive. It must first be activated. Of the various methods suggested for activation, that used by Miller seemed to offer the best source of pure active amorphous carbon. However, steam activation gives a more active carbon, but hydrogen is liberated which is strongly adsorbed and very difficult to remove. For this reason steam activation was avoided except for a few preliminary experiments. Treatment with iodine, sodium carbonate or other reagents presents similar difficulties. Some sugar was charred in platinum dishes, and ground but not passed through a sieve, heated in a quartz tube for 24 hours at about 950° and then activated by steam for 30 minutes. The charcoal was then heated for one hour more in an atmosphere of nitrogen, and allowed to cool under the same conditions. After cooling, the sample was used at once in order to avoid carbon dioxide.

Samples of this produced about the same amount of adsorption of hydrochloric acid and sodium hydroxide. The presence of sodium chloride increased the amount of each adsorbed. Since this is not in agreement with the experiments of Miller, other experiments with alkalis are being conducted and will be given in a later paper. The filtrate from sodium hydroxide solutions was slightly clouded unless a little sodium chloride was added before filtration, in which case a perfectly clear filtrate resulted. The adsorption of pure hydrochloric acid by the steam-activated charcoal was checked by titrating the chlorides according to the method of Volhard. The unactivated charcoals showed no adsorptive power. The results are given in Table I.

Activated	0	20 20	20.50	18.95
Activated	1 0	27 10		25.90

The charcoal used for the greater part of this work was prepared by heating the sugar which had been charred in platinum dishes to a temperature of 950° in 2×61 cm. quartz tubes for 24 hours. The quartz tubes were enclosed in an asbestos box and heated by five Méker burners. The tubes were packed tightly with charcoal and the ends left open until the maximum temperature was reached. This assisted in driving off any remaining adsorbed hydrocarbons. Then the ends of the tubes were fitted with glazed porcelain stoppers, and so remained until the heating was completed. The final heating was carried out in covered porcelain crucibles in an electric furnace which was kept at 1000° for 48 hours. This charcoal was then ground in an agate mortar to pass through a 200-mesh sieve, and thoroughly mixed. Charcoal prepared in this way is an active adsorbent and contains less than 0.2% of ash. A 10g. sample shaken with conductivity water and allowed to stand for 24 hours and then filtered, left a filtrate which was neutral to the common indicators.

The charcoal which had been charred with sulfuric acid was activated by heating for 24 hours in closed quartz tubes, and for 24 hours more, during which time a measured amount of air was forced through the tube, the amount of air being sufficient to burn about two-thirds of the original charge. This charcoal was also ground in an agate mortar to pass through a 200-mesh sieve. It contained less than 0.05% of ash, and also left a neutral filtrate when shaken with water and filtered.

Procedure

The balance, weights, flask, pipets and burets were calibrated according to the usual methods. Pyrex glassware was used throughout. All solutions were prepared with conductivity water. The acids and bases used were Baker's "Analyzed," and the neutral salts were Merck's "Reagent" products. All of the experiments were performed with 0.0100 *N* acid or base, prepared as follows: 50 cc. of the 0.1000 *N* solution was mixed with a definite amount of salt solution in a 500cc. graduated flask, and diluted to volume. This method gave solutions of the desired neutral salt concentration, which were 0.0100 *N* with respect to the acid or base present. For example, with hydrochloric acid, the acid in each sample was 0.01 *N*, but the concentration of the sodium chloride was increased in successive samples from 0 to 4.5 *N*; 4.5 *N* is the closest normality to the

saturation point with which it is practical to work. Before treating the charcoal these solutions were titrated with 0.01 *N* standard solution, as an assurance that the prepared solutions were exactly 0.0100 *N*.

Phenol red (phenolsulfonephthalein) was the indicator used.⁹ It was prepared from the dye according to Clark's directions.¹⁰ This indicator is extremely sensitive to carbon dioxide; consequently the solutions were all boiled before and during the titration. When dealing with alkaline solutions it was particularly necessary to boil the solutions after each addition of acid in order to determine the true end-point, since during the process of filtration they adsorb carbon dioxide.

From each solution two 125cc. portions were taken. Each portion was shaken with 1.2500 g. of charcoal in a 500cc. Erlenmeyer flask. The flasks were placed in a constant-temperature bath and kept at 25° for 24 hours. This gave ample time for equilibrium to be reached. The charcoal was then removed by filtering. A blank determination showed that the concentration of a solution was unchanged by a possible selective adsorption of the filter paper. Fifty-cc. portions were titrated again, using the 0.01 *N* standard solutions. The difference in the concentrations before and after treatment with charcoal indicated the amount adsorbed. According to this method two 50cc. portions were titrated from each sample and two samples were taken for each salt concentration. This gave four measurements for each result obtained. When unexpected results were obtained, extra samples were prepared and titrated.

Experimental Results

The results for the adsorption of hydrochloric acid are tabulated below

TABLE II

in milligram equivalents adsorbed per gram of charcoal per 100 cc. of 0.01 *N* solution. The amount of hydrochloric acid adsorbed increases rapidly with increased concentration of the sodium chloride up to 0.5 to 0.75 *N* concentration of sodium chloride. With more concentrated solutions, in respect to the salt, the increase in adsorption of the acid approaches a linear function of the increase in the salt concentration. This fact is shown graphically in Fig. 1. The milligram equivalents adsorbed are plotted as ordinates, and the concentrations of a salt, expressed in terms of normality, are taken as abscissas.

The presence of sodium nitrate affects the adsorption of nitric acid in the same manner. The nitric acid is adsorbed to a greater extent than the hydrochloric acid.

Sulfuric acid in the presence of sodium sulfate exhibits the same general type of curve. However, the amount adsorbed decreases as the amount of sodium sulfate increases. This was contrary to the expected results, and contrary to the results obtained by Michaelis and Rona. Conse-

quently, this work was repeated and the same results were obtained the second time. Also this part of the experiment was repeated with a different type of charcoal, as will be discussed in detail later.

However, the results again showed a decrease in the adsorption of sulfuric acid, upon increasing the concentration of sodium sulfate.

The results of these experiments on the adsorption of acids in the presence of a common ion are shown in graphic form in Fig. 1.

Fig. 1. Adsorption of acids in the presence of a common ion by sugar charcoal - heat charred

In order to show more clearly the difference in the adsorption of the acid further determinations were made. The charcoal prepared by treating with sulfuric acid was used for these determinations. It was more active in adsorbing acids and, therefore, accentuates their differences.

Mixtures of two acids, containing 0.005 *N* solutions in respect to each acid, or of a total acidity of 0.01 *N*, show an adsorption less than that of the more active acid alone, but more than that of the less adsorbed acid. One g. of this charcoal adsorbs from 100 cc. of 0.01 *N* solution 0.1696 mg. equiv. of sulfuric acid, 0.2549 mg. equiv. of hydrochloric acid and 0.3232

mg. equiv. of nitric acid. From a mixture of nitric and sulfuric acids, 0.2959 mg. equiv. is adsorbed; from a mixture of sulfuric and hydrochloric acids, 0.2527 mg. equiv. is adsorbed.

Acids in the presence of concentrated solutions of salts without a common ion were also treated, and the amount of adsorption measured. The complete list is tabulated in Table V, and shown in graphic form in Fig. 2.

It was believed that it would be interesting to determine the adsorption of acids and bases in the presence of a common ion, using another type of charcoal. In general the same method was carried out, using Merck's (acid purified) blood charcoal which had been carefully heated to drive off adsorbed gases.

The results are tabulated below, and are shown graphically in Fig. 3.

In all cases the same relative amounts were adsorbed, which resulted in similar curves to those for pure sugar charcoal. Hydrochloric acid and sodium hydroxide show an increased adsorption as the concentration of the sodium chloride increases. Sulfuric acid shows a decrease as the concentration of the sodium sulfate increases. Sodium acid sulfate shows a rapid decrease with increased concentration of sodium sulfate.

Fig. 3.—Adsorption experiments with blood charcoal.

Discussion and Interpretation of Results

The adsorption of an ion gives a charge to the colloidal particle which attracts to it, although less strongly, the oppositely charged ion of the electrolyte. The resultant effect is a reversible equilibrium of electrostatic

forces. There is the attraction of the colloidal particle for the ion which it adsorbs. Also there is a tendency for the oppositely charged ion to diffuse through the solution, attracting to it the adsorbed ion. The direction of this last attraction is away from the colloidal particle.

The effect of the attraction away from the colloidal particle will depend upon the degree to which the ion is adsorbed. Langmuir's explanation for the adsorption of gases by charcoal¹¹ undoubtedly applies here. "Between the atoms of carbon, there must be spaces of all possible sizes and shapes, some just too small to hold a gas molecule, others big enough to hold one but not hold two, etc. There are some spaces in which a molecule would be closely surrounded by carbon atoms on nearly all sides, whereas in other places a molecule would be able to hold on to only a single carbon atom."

There is a stage in adsorption which is approximately irreversible. This has been pointed out by Miller in his description of the difficulty with which part of the adsorbed acid is removed from the charcoal by washing with pure solute. This stage may be pictured as the part of the hydrogen ions which are surrounded on nearly all sides by carbon atoms. Of course if these hydrogen ions cannot be removed by washing, the anions must also remain in the charcoal or in close proximity to it. In the case of hydrochloric acid, for example, when the increased adsorption in the presence of sodium chloride occurs, the same picture is applicable. The excess of chloride ions in the solution decreases the tendency of the chloride ions of the hydrochloric acid to diffuse; consequently, its attraction upon the hydrogen ion away from the particle is lessened. This allows the hydrogen ions adsorbed to become more firmly attached to the carbon, by penetrating further into the spaces between the carbon atoms. This penetration leaves room for more hydrogen ions to be adsorbed, although less firmly, at places nearer the surface of the carbon particle.

In this investigation it was found that 0.01 *N* sodium hydroxide solutions, when filtered, remain cloudy in appearance even after all possible charcoal was filtered out. Evidently the charcoal was peptized by the sodium hydroxide to form a colloidal dispersion. However, when solid sodium chloride was added to this cloudy filtrate, the dispersed charcoal rapidly settled out, and was easily filtered. Evidently the excess of sodium ion decreases the ionization of the sodium hydroxide so that the adsorbed hydroxyl ions are electrically neutralized by the sodium ions, and the colloidal particles are discharged and precipitated. The adsorbed sodium hydroxide remains on the particles when they are precipitated. This is shown by the fact that removing the charcoal decreases the alkalinity of the solution. On this basis the charcoal particles should be dispersed again when the precipitating agent, sodium chloride, is removed by wash-

¹¹ Langmuir, *THIS JOURNAL*, 38, 2286 (1916)

ing, because of the renewed dissociation of the adsorbed sodium hydroxide. This is indeed the case.

There is no evidence discovered in this work for assuming hydrolysis of the neutral salt. There is, rather, evidence that hydrolytic adsorption does not take place. Sodium chloride increases the adsorption of both the hydrochloric acid and sodium hydroxide. Therefore, if it were due to hydrolytic adsorption we should have hydrochloric acid adsorbed preferentially by charcoal in the case of hydrochloric acid and sodium chloride, and sodium hydroxide in the case of sodium hydroxide and sodium chloride, which would be very mysterious indeed.

Since in a saturated solution of sodium chloride it is not possible to suppress entirely the ionization of 0.01 *N* hydrochloric acid, a continual increase in adsorption with increased concentration of sodium chloride is to be expected. Michaelis states that a maximum adsorption is reached when acid-salt mixtures up to 2 *N* with respect to sodium chloride are used. However, up to and including 4.5 *N* solutions with respect to sodium chloride, no evidence of a maximum adsorption of hydrochloric acid was discovered. The work included not only adsorption by sugar charcoal, but also Merck's blood charcoal, as used by Michaelis.¹² Evidently the thermodynamic basis upon which his theory of adsorption rests does not fit the experimental facts.

The adsorption of nitric acid from sodium nitrate solutions is exactly analogous to the case already considered. The fact that nitric acid is more strongly adsorbed than hydrochloric acid shows that although both the nitrate and chloride ions are less strongly attracted to the charcoal than are the hydrogen ions, the nitrate ion is more strongly attracted than the chloride ion.

The decrease in the adsorption of sulfuric acid in the presence of sodium sulfate can be accounted for on the basis of the above theory. The reaction $\text{H}_2\text{SO}_4 + \text{Na}_2\text{SO}_4 = 2\text{NaHSO}_4$ undoubtedly takes place to some extent. The greater the concentration of the sodium sulfate, the more sodium acid sulfate will be formed. In an excess of sodium sulfate, the sodium acid sulfate will liberate very few free hydrogen ions. Consequently, the higher the concentration of the neutral sulfate, the fewer the hydrogen ions in the solution available for adsorption.

The 0.01 *N* solution of sodium acid sulfate alone is quite noticeably adsorbed. However, when sodium sulfate is added, the decrease in adsorption with increased concentration of added salt is much more rapid than in the case of sulfuric acid. Here again the results obtained are in disagreement with those obtained by Michaelis. His data show an increase in the adsorption of sulfuric acid in the presence of increased concen-

¹² Svedberg, "Colloid Chemistry," Chemical Catalog Co., Inc., New York, 1924, p. 178.

tration of the sulfate ion. Consequently, samples of such mixtures were treated with blood charcoal, as well as with the sugar charcoal, and the decrease in the adsorption was again demonstrated.

Furthermore, dealing with another type of charcoal, that charred with sulfuric acid, it was observed that 1 *N* sodium sulfate decreases the adsorption of nitric acid. One g. of charcoal adsorbed 0.3232 mg. equiv. of nitric acid from 100 cc. of 0.01 *N* solution. With the same acid concentration, containing sodium sulfate, 0.2229 mg. equiv. is adsorbed. Some of the hydrogen ions are tied up with the sodium acid sulfate in the presence of the excess sodium sulfate, according to the reaction $\text{HNO}_3 + \text{Na}_2\text{SO}_4 = \text{NaHSO}_4 + \text{NaNO}_3$. Consequently, there is less adsorption than with nitric acid alone.

When the adsorption from a mixture of 3.0 *N* sodium chloride and 0.01 *N* nitric acid is determined, an amount less than the adsorption of free nitric acid is again shown. This is to be expected because of the reaction $\text{HNO}_3 + \text{NaCl} = \text{HCl} + \text{NaNO}_3$. Hydrochloric acid is less adsorbed than nitric acid, but the adsorption of the hydrochloric acid formed is augmented by the excess sodium chloride present. The amount adsorbed is, therefore, greater than the adsorption of pure 0.01 *N* hydrochloric acid, but slightly less than that of pure 0.01 *N* nitric acid.

Sodium nitrate, 3.0 *N* with 0.01 *N* solutions of either hydrochloric or sulfuric acid give an adsorption greater than that of any of the pure acids. The results are similar to the adsorption of nitric acid in the presence of concentrated solutions of sodium nitrate.

The results of the adsorptions of mixed acids are not surprising, but give further evidence of the relative adsorbability of the acids considered.

Summary

1. The phenomena of adsorption are explained on the basis of the attraction of ions by colloidal particles and the effect of mass action upon this attractive force.
2. It has been demonstrated, as has been generally conceded, that the hydrogen ions of inorganic acids and the hydroxyl ions of inorganic bases are the most strongly adsorbed.
3. The nitrate ion is more strongly adsorbed than the chloride ion, and the chloride ion is more strongly adsorbed than the sulfate ion.
4. Relative results can at any time be duplicated, but it is difficult to obtain separately prepared charcoals with the same degree of activation.
5. There is no evidence of hydrolytic adsorption of neutral inorganic salts in the presence of inorganic acids or bases.
6. There is no maximum adsorption of acids in the presence of a salt with a common ion.

THE MOVING-BOUNDARY METHOD FOR DETERMINING TRANSFERENCE NUMBERS. VI. FURTHER DEVELOPMENTS IN EXPERIMENTAL TECHNIQUE

BY D. A. MACINNES, IRVING A. COWPERTHWAITÉ AND T. C. HUANG

RECEIVED MAY 11, 1927

PUBLISHED JULY 5, 1927

1. Introduction

Many of our experimental methods in the use of the moving boundary for measuring transference numbers have been described in the earlier papers of this series.¹ Recently, however, we have made a number of changes and improvements in the apparatus that seem worthy of record as they have resulted in greatly increased accuracy and convenience, in the possibility of use of the method through wider ranges of concentration and materials, and in the use of the method under unfavorable circumstances.

2. Changes in the Design of the Cell

All of our recent work has been carried out with the type of cell designed by MacInnes and Brighton^{1c} in which the boundary is formed by means of a shearing motion. The improved apparatus is shown in Fig. 1. The disks B and C are now made of plate glass, instead of the hard rubber formerly used. The glass does not warp after a little use as the rubber did. It also has a smoother surface, and its transparency is frequently of service. The channels, etc., in the surfaces of the plates that are in contact were etched out with hydrofluoric acid.

Since the motion of a boundary through 10 cm. of the measuring tube involves a volume of only 1.7 cc., and in our most recently constructed cell only 0.32 cc., it is evident that all precautions must be taken to prevent slight volume changes in the apparatus that would, ever so slightly, affect the motion of the boundaries. In pressing the lubricated plates together a small amount of air was included under a slight excess of pressure. This was occasionally sufficient to form a bubble at the junction of the measuring tube and apparently produced irregularities in the readings. This difficulty was overcome by placing a vent, F in Fig. 1, which releases the pressure by leading off the excess of air from the space between the plates to a point above the level of the thermostat water.

It has been our practice to have one of the electrode vessels completely

¹ (a) MacInnes and Smith, *THIS JOURNAL*, **45**, 2246 (1923). (b) Smith and MacInnes, *ibid.*, **46**, 1398 (1924). (c) MacInnes and Brighton, *ibid.*, **47**, 994 (1925). filled with solution. The moving-boundary results are corrected, according to the method of Lewis,² for volume changes at this closed end of the apparatus. The other electrode vessel contains a bubble of air to allow for possible expansions and contractions during the electrolysis. Originally this bubble was at the top of the vessel which projected into the air and was thus exposed to changes of temperature. This was probably the cause of some irregularities in our measurements. At present, however, one of the tubes holding the electrodes is left hollow and holds a small volume of air under the solution where it encounters a uniform temperature.

An added convenience, which makes possible the turning Disk B over Disk D with a minimum of mixing due to shaking, is furnished by the chain and sprocket arrangement also shown in Fig. 1. The brass Disk A which extends beyond the water of the thermostat is connected to a small sprocket S by means of a brass tube which encircles the upright of the stand. The sprocket engages a chain which is passed around Disk B. The chain is held in place by means of a rubber band which is slipped over a strip of brass holding a pin which, in turn, is inserted into a hole bored in the glass disk. Thus by turning the brass Disk A, the glass Disk B can be swung into place.

The convenience in measuring the time required in the passage of a boundary between graduations of the measuring tube has been greatly increased by substituting a Veeder magnetic counter for the watch previously used. The counter is operated once per second, by an accurate pendulum clock. Electrical contacts with the pendulum have been avoided by making the pendulum interpose a screen between a light and photo-electric cell once per second. By amplification this is made to operate the electric counter. The latter is started when the boundary passes the first graduation mark, and readings are made directly in seconds thereafter. A large amount of burdensome computation (subtractions, and changing of hours and minutes into seconds) is thus avoided.

Fig. 1.

3. The Effect of Vibration

In our earlier experiments in Cambridge we found that erratic results were obtained if there were a large difference between the densities of the leading and indicator solutions, such as exists between silver or cesium nitrates and lithium nitrate. The boundary usually started at nearly the correct rate but gradually slowed down toward the end of the determination. This effect is undoubtedly due to mixing caused by waves, over the surface of the boundary, generated by external vibrations. By exercising ordinary care to remove sources of vibration, results were obtained even with silver solutions. However, after moving the apparatus to New York City the vibrations were found to be intense enough to make the moving-boundary method quite useless, even for pairs of solutions without large differences in density.

This serious difficulty was overcome, after a series of preliminary experiments, by the use of a modified Julius suspension for the thermostat. A diagram of the arrangement is shown in Fig. 2. The thermostat is placed on a cast-iron plate, *a*, from which four heavy bolts extend to about the level of the center of gravity of the suspended system. From these bolts extend four 4 cm. heavy coil springs, *c*, about 45 cm. long which, in turn, are supported by four light ropes, *d*, tied to hooks fixed in a heavy beam in the ceiling. Under these conditions no external vibrations of any strength reach the thermostat, as is shown by the steadiness of a beam of light reflected from the surface of a dish

Fig. 2.

of mercury. Although these are ideal conditions for the progress of the measurements it is necessary to commence the determination, that is, to turn the electrode vessels into place over the measuring tube, without starting vibrations in the system. This we have accomplished as follows. The lower edge of the suspended system is hung very near to the table top *t*. From the center of the cast-iron plate, *a*, extends an iron rod, *f*, which passes through a hole in the table top and to which is attached a rope which is connected to a foot treadle (not shown in the figure). By pressing on this treadle the suspended system is temporarily placed in contact with the table. Choosing a moment when vibration is feeble, the boundary is made by turning Disk B (Fig. 1) on Disk C. The treadle is then carefully released. This can be done without causing the suspended system to swing.

It has been our frequent observation that a boundary which starts at an incorrect rate (due presumably to a very slight initial mixing of the solutions) will gradually approach the correct rate as the experiment proceeds, unless there is an additional source of disturbance. It appears, therefore, that the vibration during the time that the boundary is being formed and the suspended system is released cannot have an appreciable effect.

4. Experiments with Rising Boundaries

So far all our work has been carried out with indicator solutions which are lighter than the solution of which the transference number is to be measured. The indicator solution must therefore be on top of the leading solution and the boundary must descend during the determination. It seemed probable that a greater range of indicators would be available, including, possibly, some colored materials which might be visible at great dilutions, if a cell could be constructed which would utilize indicator solutions which are heavier than the measured solution. This would, of course, involve rising boundaries. Experiments were therefore carried out with an apparatus which was substantially the cell shown in Fig. 1 inverted, although a number of details had to be changed.

Observations were made on the boundaries KMnO_4 0.07 *N* \rightarrow KCl 0.1 *N*, and BaCl_2 0.07 *N* \rightarrow KCl 0.1 *N*. In both cases the boundaries were relatively sharp at the start, although somewhat convex upward. As they progressed, however, they became increasingly diffuse and instead of maintaining a steady motion as would be expected, the current being kept constant, both boundaries slowed down. It was evident that some additional condition governed the phenomenon when the boundaries were rising.

With the permanganate-chloride boundary there was another effect which was visible, due to the color of the indicator solution. A representation of the effect is shown in Fig. 3, in which the heavily shaded region, C, represents the portion of the tube containing the potassium permanganate indicator solution and the unshaded, B, the potassium chloride solution. Rising from the boundary was a faintly pink region of chimney shape, the color of which became more intense as the electrolysis proceeded, and finally not only this region but all of the potassium chloride region became colored. It immediately became of interest to find out whether a similar effect is to be observed with a descending boundary, and it was a relief to find that with permanganate as the leading solution and an acetate as indicator, a perfectly sharp boundary was formed with no pink color in the acetate solution. Furthermore, the boundary moved at the normal uniform rate.

The explanation of the disturbing effect with rising boundaries appears to be as follows. Since the indicator solution contains ions which have lower mobility than the ions of corresponding charge in the leading solu-

Fig. 3.

tion, and is further diluted according to the relation^{1a,3} $C/T = C'/T'$, the conductance of the indicator solution must be lower than that of the measured solution. The result is therefore that due to the higher potential gradient, more heat is generated in the indicator solution than in the solution it follows. The effect shown in Fig. 3 is due to the fact that a small amount of the potassium chloride solution immediately in contact with the boundary became warmed and rose, carrying a small amount of permanganate with it. A similar effect must have occurred in the barium chloride-potassium chloride boundary, but it was not visible. In the case of the descending boundary, on the other hand, the warmer indicator solution is on top, and the difference of temperature tends to keep the two solutions separate, if it has any effect at all.

It is evident, therefore, that in all moving-boundary measurements the solution of lower conductance must be on top. Some of the early work with the moving boundary must be in error on account of failure to observe this effect. An additional effect of heat generated in the apparatus will be given in Section 6.

5. The Visibility of the Boundary

In all our measurements we read, to the nearest second, the time when the boundary passes a given graduation mark. An increase of accuracy has been attained by graduating the tube as is shown in Fig. 4. The graduation marks extend on either side, one-fourth or less of the distance around the tube, leaving a clear space in front and back. In this way the boundary is always visible, and is never covered by the graduation mark. With faint boundaries, such as are obtained with dilute solutions, this arrangement is entirely necessary.

Fig. 4.

The possibility of distinguishing the junction of two transparent solutions depends upon the differences in their refractive indices. The arrangement now used for viewing the boundary is shown diagrammatically in Fig. 5. An electric lamp E is shaded by a metal screen except for a slit, $a-b$ (seen edgewise in the figure) which is covered by a translucent screen. By means of a rack, sprockets and chain this slit can be moved vertically. Ignoring the effects of the glass walls of the thermostat $M-M'$ and $N-N'$ and of the measuring tubes, the path of a beam of light from the lower edge b of the illuminated slit is b, B, J . Thus, the edge b , viewed *through the boundary*, appears as if it were at b' . At a certain limiting value of the angle $b B b'$ we have the condition for total reflection. At this point the boundary appears as a sharp dark line at b' with an illuminated area below it due to the fact that the illuminated slit can also be viewed directly through the lower solution. The apparent separation

³ C , C' , T and T' are, respectively, the concentrations and transference numbers of the measured and indicator solutions

of the direct and refracted images depends on the differences of the indices of refraction of the solutions meeting at the boundary.

A very surprising increase in the visibility of boundaries is obtained by the simple device of placing a lens at the point J as shown in the figure. The lens must have a focal length reaching only to the region of the boundary. The effect of this arrangement is to throw the directly viewed edge of the slit *b* out of focus. The edge of total reflection, which constitutes the boundary, can thus be much more readily distinguished. Other optical systems that we have tried have been less effective than the simple one just described.

6. Conditions Governing "Adjustment"

As explained in previous papers in this series, the ions of the leading solution and the indicator move at the same rate when the solutions are adjusted to the condition

$$C/T = C'/T' \quad (1)$$

which must be, in general, obtained by a series of experiments. A curve of the apparent transference numbers as ordinates against the indicator concentrations C' as abscissas takes an upward slope in the dilute region, then a horizontal portion followed by a slope for more concentrated indicators. The correct transference number, and the values fulfilling the condition of Equation 1 are on the flat portion of the curve.^{1d} Now the relative width of this flat portion is an important matter, since it determines the number of determinations that must be made in order to establish the shape of the curve. According to Kohlrausch⁴ and others

⁴ Kohlrausch, *Ann. Physik*, **62**, 209 (1897).

the condition represented by Equation 1 should establish itself automatically, no limits of initial concentration being stated. However, we have found in general that this can only be relied on for deviations of 3 to 5% from the correct concentration. There are apparently additional influences, including diffusion, that limit the range of adjustment. We have found, for one thing, that adjustment is considerably modified by the amount of heat developed in the measuring tube. Some experiments already published^{1b} have shown that with an apparatus involving the use of a wide tube (10 mm.) the flat spot in the curve nearly disappeared. In that case, due to the relatively low ratio of external surface to area of tube, the heat had little opportunity to be conducted away. We have recently observed much the same effect with a 6mm. tube with more concentrated solutions, and thus necessarily higher currents than were used in the earlier experiments. On the other hand, we have found adjustment over wide ranges of indicator concentrations under two conditions, (a) very dilute solutions, and (b) solutions of electrolytes having high equivalent conductances. In the first of these cases it is evident that little heat is developed because small currents pass through the apparatus. The measurements with highly conducting solutions (for example, 0.1 *N* hydrochloric acid or 0.1 *N* nitric acid) can be explained in the same way. Since the resistance is relatively low, less heat is generated. However, this latter case is complicated by the fact that the solution is followed by an unusually dilute indicator solution (0.03 to 0.05 *N*) in which, due to the high potential gradient, the heating effect must be unusually large. However, this hotter solution is on top rather than on the bottom in contrast to the experiments described in Section 4, so that the small difference of temperature apparently increases the stability of the system rather than otherwise.

For use with solutions above 0.1 *N* we have constructed a cell with a thin-walled measuring tube with an internal diameter of only 2 mm. At the same rate of motion of the boundary this smaller tube requires only one-ninth of the current used in the 6mm. tube, whereas the surface exposed is one-third. A distinct increase of the range of indicator concentrations yielding adjustment has been observed, as would be expected. However, other factors not yet clearly understood affect adjustment. We expect to make this matter the subject of future investigations.

7. The Transference Number of 0.05 *N* Silver Nitrate Solution

The data we have accumulated on transference numbers will be published in an article dealing with the question of the ionization of strong electrolytes. It may be of interest, however, to give an example of the precision attainable, under favorable circumstances, by the moving-boundary method. A plot of the data on 0.05 *N* silver nitrate solution is

given in Fig. 6, in which the observed transference numbers are plotted as ordinates and the indicator concentrations as abscissas. The concentration of the indicator solution (lithium nitrate) varied from 0.0385 *N* to 0.0410 *N*. It will be seen that adjustment was attained through nearly all of this range within about 0.02%. A slight drop in the transference number can be observed in the region of the dilute indicator solutions. Experiments were not carried out at higher values of the indicator solution than those shown, but from analogy to other cases studied the curve would eventually ascend. The value for the transference number obtained, 0.4664 at 25°, is lower than published values by the Hittorf method, which are nearer 0.470.

Fig. 6.

Summary

Improvements in the moving-boundary apparatus for determining transference numbers, leading to greater accuracy and convenience in the use of the method, are described.

The measurements have been found to be much influenced by vibrations, particularly where there is much difference in density of the solutions at the boundary. Our method for eliminating this difficulty is outlined.

Experiments are described with indicate that boundaries must be descending during the determinations. Ascending boundaries give rise to heat effects which cause mixing.

The conditions governing the visibility of boundaries are outlined.

Some of the factors governing "adjustment," that is, the dependence of the motion of the boundary on the indicator concentration, are outlined.

The precision of the method now attainable is shown by measurements of the transference number of 0.05 *N* silver nitrate solution.

THE DECOMPOSITION OF QUATERNARY AMMONIUM HYDROXIDES. ALKOXYMETHYLDIETHYL-METHYL- AMMONIUM HYDROXIDES

BY T. D. STEWART AND JOHN G. ASTON

RECEIVED NOVEMBER 10, 1926

PUBLISHED JULY 5, 1927

The thermal decomposition of quaternary ammonium compounds usually proceeds according to one of three reactions.

The work of earlier investigators has been reviewed by v. Braun¹ who concluded that if the four R groups are not alike, the group which appears as RX (Equation 1) upon decomposition will depend upon the relative reactivities of the groups present. He arranged certain groups in the decreasing order of their reactivities as follows: allyl, benzyl, methyl, ethyl, propyl, *isobutyl*, *iso-amyl*, phenyl.

v. Braun also determined the order of reactivity of the various groups for the hydroxides (Equations 2 and 3) and found certain differences from the order given for other negative ions. In the order of decreasing reactivity he found them to be allyl, benzyl, ethyl, propyl, *iso-amyl*, methyl, *isobutyl*, phenyl. In another series of experiments he determined the effect of the length of the carbon chain and the effect of certain substitutions upon the tendency of the group to split off as compared to the methyl group, and concluded that the symmetry of the ethylene formed, together with certain factors regarding conjugation of the unsaturated groups, determined the velocity of the rupture.

Discussion of Results

The present paper deals with the decomposition of quaternary bases of the type $[ROCH_2-NR_3]OH$. Robinson and Robinson² distilled a solution of butoxymethyldiethyl-methylammonium hydroxide and found only methyldiethylamine among the basic decomposition products. This result has been confirmed in the case of the ethoxy derivative and would appear to indicate a higher degree of reactivity for the $(RO-CH_2-)$ group than for the ethyl group.

The fact that the tertiary bases hydrolyze readily in aqueous acid according to the equation $R'O-CH_2-NR_2 + H_2O + H^+ \longrightarrow R'OH + CH_2O + (R_2NH_2)^+$ suggests that this abnormal reactivity of the alkoxy-methyl group is to be associated with hydrolysis of the ether linkage. However, the quaternary salts decompose very slowly or not at all in

¹ v. Braun, *Ann.*, **382**, 1 (1911).

² Robinson and Robinson, *J. Chem. Soc.*, **123**, 532 (1923).

aqueous acid or dilute alkaline solutions at 100° and it will be shown that the same factors which cause the rupture from nitrogen of the alkoxy-methyl group also effect the rupture of the other alkyl groups. It will also be shown that the proportion of alkoxy-methyl to methyl or ethyl groups which split off is a function of the temperature.

The decomposition of ethoxymethyldiethyl-methylammonium hydroxide has been studied under three conditions. First, a solution of the base was evaporated slowly (during ten days) in a vacuum desiccator at room temperature; second, a similar solution was evaporated more rapidly (two days) at room temperature in a vacuum; third, a solution of the hydroxide was concentrated by distillation at atmospheric pressure.³

The results of the three experiments can be expressed by two equations.

The only difference between the first and second experiment was the time required for the decomposition. The products found were practically identical in the two cases, and indicated that 18.5% of the reaction took place according to Equation 4, and 81.5% according to Equation 5. The results of the third experiment, at the higher temperature, indicated that at least 90% of the reaction took place according to Equation 4.

The rate of rupture of the alkoxy-methyl and of the ethyl groups is thus the same function of the rate of pumping or rate of evaporation of water from the solution. As a solution of the base becomes concentrated at room temperature, no decomposition occurs until the sirupy liquid approaches a composition corresponding to between a tetra- and penta-hydrate. The reaction begins suddenly, proceeds at a constant rate, depending upon the surface exposed and the pressure, and stops as suddenly as it started.⁴

The relative activities of the three groups at room temperature are as follows: $\text{C}_2\text{H}_5 > \text{C}_2\text{H}_5\text{OCH}_2 > \text{CH}_3$. Above 100° the relative reactivities are $\text{C}_2\text{H}_5\text{OCH}_2 > \text{C}_2\text{H}_5 > \text{CH}_3$. It is apparent that the order of reactivity may be changed by a change in the temperature at which

³ This was the method used by nearly all of the previous investigators.

⁴ In one instance a sample contained in a weighing bottle was slowly evaporated for a week. It started to give off gas (ethylene and amines) within a given half-hour, and while held at constant pressure gave off gas bubbles only from the surface at practically constant rate, as measured by the time necessary to build up to a given pressure or as measured in other instances by a sulfuric acid bubbler in the line. The apparent equivalent weight remained constant throughout the decomposition.

the decomposition is carried out, and that the reactivity of the ethoxymethyl group is closer to that of ethyl than to that of methyl.

The decomposition of *isobutoxymethyl*-trimethylammonium hydroxide, $C_4H_9OCH_2-N(CH_3)_3OH$, under the same conditions as in the second experiment described above, yielded trimethylamine as the only volatile base.

The question of whether a tetrahydrate, a lower hydrate, or anhydrous molecule is the species which decomposes cannot be answered. If the evaporation and decomposition at room temperature proceed at a higher total pressure, and therefore more slowly, bubbles form throughout the mass instead of solely at the surface, suggesting that whatever is formed by evaporation at the surface has time to diffuse to some depth (about 1 to 2 cm.) before decomposing, or that water from the body of the solution has time to diffuse to the surface so that the composition is constant throughout the mass. In such a case the equivalent weight more nearly corresponds to that of a tetrahydrate than in the case of a more rapid evaporation where the surface layer only is kept at a composition which promotes decomposition. At a very low pressure (0.001 mm.) and temperature (-20°), evaporation proceeds slowly without apparent bubbling, but as soon as the temperature is raised, even at atmospheric pressure, evolution of gas begins. These facts seem to indicate that hydrate formation stabilizes the quaternary ion in the presence of hydroxide ion.⁵

Another important fact, namely, that hydroxide and carbonate ions cause the formation of ethylene as well as of alcohol, must be accounted for and possibly connected with the relative rates of rupture from the nitrogen of the various groups under consideration. It seems probable that the instability of an "onium" compound lies in the tendency of the charge on the central atom to become neutralized at the expense of a shared electron with the consequent loss of a positive ion.

The ease with which a quaternary ammonium compound will decompose will then depend upon two factors; first, the tendency of the nitrogen atom to lose the positive charge, with the loss of one of the groups as a positive ion, and second, the reluctance of the bound groups to split off as the positive ion. This reluctance is less if the presence of certain groups (ethylene bonds, oxygen atoms) may serve to distribute the positive charge along the group in question, and hence reduce the intensity of the positive charge upon the nitrogen atom. Another means of reducing the charge upon the nitrogen or upon the carbon atoms is the dissociation of a hydrogen atom. A reactive hydrogen upon an atom sufficiently

⁵ Very few quaternary bases decompose rapidly in dilute aqueous solution, even at 100° . Of these may be mentioned those of the type $[R_3NOR']OH$, which in dilute aqueous solution at room temperature slowly decompose to give the tertiary amine R_3N , water and the aldehyde or ketone corresponding to the radical R' . The substance $[C_6H_5CH_2CH_2-N(CH_2)_3]OH$ also decomposes in dilute solution, upon heating.

near the nitrogen, through its oscillation if not actual ionization, could in effect reduce the intensity of the charge upon the nitrogen and carbon, and facilitate the rupture reaction. The role of the hydroxide ion then becomes clear. It acts either as an agent to aid in the removal of hydrogen ion from the molecule, or to replace the tertiary amine nitrogen in the quaternary ion. The former reaction explains its specific action in hastening decompositions which do not take place in acidic solution and in causing the formation of ethylenes.⁶

The decomposition does not involve ions, in the sense that there exists at any time appreciable amounts of either alkyl or hydrogen ions in the solution, or that either of these ions is formed as a *reversible* first step in the decomposition. We may rather look upon the decomposition, when an ethylene is formed, as preceded by the *simultaneous* loosening of the carbon-nitrogen and carbon-hydrogen bonds. This is followed by the simultaneous loss of hydrogen ion, rupture of the carbon-nitrogen bond, and rearrangement of the carbon residue to a stable ethylene. The relative rates of the decompositions will then depend upon the capacities of the various groups to reduce the intensity of the positive charge through minor rearrangements of electrons and protons within the group. The loss of hydrogen ion to form water, in the presence of hydroxyl ion, will cause a more rapid rupture of a given group. If this last reaction could be excluded, it is probable that the relative rates of decomposition of different groups in salts and in quaternary bases would be identical.

The stabilizing effect of water upon the quaternary ion may be attributed to the same sort of factor that promotes the decomposition. The hydration of the ion serves to distribute the positive charge over what is essentially a larger molecule, thereby lowering the intensity of the charge upon the nitrogen. There is, therefore, less tendency for the carbons or hydrogens to assume a positive charge.

Experimental Part

Decomposition of Ethoxymethyldiethyl-methylammonium Hydroxide at Room Temperature

Expt. 1. Qualitative Decomposition.—A solution of ethoxymethyldiethyl-methylammonium hydroxide was prepared from 20.15 g. (0.074 equivalent) of the iodide and a slight excess of the calculated quantity of silver oxide. It was evaporated at room temperature in a vacuum desiccator over calcium chloride to a volume of about 25 cc., then transferred to a tared weighing bottle and the evaporation continued in a vacuum over phosphorus pentoxide. The solution became viscous and had no odor of amines. When the weight of the residue reached 15.80 g., a froth was observed on the surface, and amine and formaldehyde odors became noticeable. A sample taken at this point, when titrated with standard acid, using phenolphthalein as indicator, showed the

⁶ See Lewis, "Valence and the Structure of Atoms and Molecules," Chemical Catalog Co., New York, 1923, p. 135.

equivalent weight to be 248, and the 15.80 g. to contain 0.0636 equivalent of base. The equivalent weight calculated for the tetrahydrate of the base is 235.

The decomposition was continued in a vacuum, the pressure rising at a constant rate from 2 mm. to about 25 mm. in two days. The cessation of the decomposition was abrupt at the end of ten days, leaving a liquid residue. The decomposition products were isolated as follows. Samples of gas aspirated from the desiccator were shown to be a mixture of ethylene and air by the usual methods of absorption and combustion. Most of the amines were contained in the acid drying agent and were recovered by the addition of alkali and by distillation into hydrochloric acid. The pure, dry hydrochloride weighed 5.14 g.

Anal. (Volhard). Calcd. for $C_5H_9NHCl \cdot Cl$, 37.15; for $C_5H_{13}NHCl$, 28.71. Found: 35.25.

The analysis corresponds to 18.5 mole % of methyldiethylamine hydrochloride and 81.5 mole % of methylethylamine hydrochloride, shown also as follows. A 4.34 g. sample of the mixed hydrochlorides (containing 0.00431 equivalent of chlorine) was separated by the method of Hinsberg⁷ into the tertiary amine and the benzene sulfonamide of the secondary amine. The yield of tertiary amine was 0.000915 equivalent, or 21% of the total amine in the mixed salts. The platinum double salt decomposed sharply at 230°.

Anal. Calcd. for $(C_5H_{13}NH)_2PtCl_6 \cdot Pt$, 33.37. Found: 33.33.

The yield of dry, liquid methylethyl benzenesulfonamide was 5.76 g.

Anal. (Kjeldahl). Calcd. for $C_9H_{13}NSO_2$: N, 7.04. Found: 6.96.

Upon hydrolysis, the amide yielded 2.08 g. of an amine hydrochloride; *m p*, 126–129.5°.

Anal. (Volhard) Calcd. for $C_5H_9NHCl \cdot Cl$, 37.15. Found: 36.90.

The chloroplatinate decomposed at 208–208.5°.

Anal. Calcd. for $(C_5H_9NH)_2PtCl_6 \cdot Pt$, 36.96. Found: 36.96.

The amines are thus methyldiethylamine and methylethylamine.⁸ The proportions of the two given by the chlorine analysis of the mixed salts are probably accurate to about 1%.

The residue from the decomposition was shown to contain salts of the undecomposed base by preparation and analysis of the chloroplatinate. When recrystallized from 50% alcohol the chloroplatinate decomposed at 223.5°.

Anal. Calcd. for $(C_5H_{10}ON)_2PtCl_6 \cdot Pt$, 27.87. Found: 28.00.

The salts were probably the bicarbonate and formate.

Expt. 2. Quantitative Decomposition.—A solution containing 0.0371 equivalent of ethoxymethyldiethyl-methylammonium hydroxide was prepared and concentrated as above. Its equivalent weight was 267 when the decomposition began. As soon as decomposition became evident, the weighing bottle and contents were sealed into a 100cc. tube (Fig. 1), which was sealed to a system consisting of a liquid-air trap (3 cm. \times 35 cm.) connected, through a tube containing phosphorus pentoxide, to a hand-operated Töpler pump. The line was pumped out by means of the Töpler pump to 2 mm., at which pressure the liquid in the weighing bottle started to boil. This boiling soon ceased. The system was evacuated to 0.5 mm. At this pressure vigorous decomposition took place and continued for 52 hours.

⁷ Hinsberg, *Ber.*, **38**, 906 (1905).

⁸ The chloroplatinates decompose, respectively, at 231° (Ref. 2) and 207–208° [Beilstein, vol. 1, p. 1125]. Hinsberg [*Ann.*, **265**, 180 (1891)] describes methylethylbenzene sulfonamide as a liquid.

After 52 hours, the decomposition stopped as suddenly as it had started, very little material remaining. The liquid air around the trap was replaced by a mixture of solid carbon dioxide and ether. This allowed the ethylene to boil out of the trap and the pressure in the line rose to about $\frac{2}{3}$ atm. The system stood overnight in this condition in order to allow time for the formaldehyde to polymerize. The outlet from the pump was then connected to an aspirator (Fig. 2) filled completely with mercury. The ethylene was pumped out of the line into the aspirator until the residual pressure was

Fig. 1.

11 mm., the displaced mercury being collected in a weighed receiver.⁹ The pressure in the aspirator was finally adjusted to atmospheric pressure by leveling the mercury surfaces in the bulb and reservoir of the pump at the three-way stopcock. During the process the adjustable tip forming the outlet of the aspirator was kept below the mercury surface in the receiver, the latter being kept below the mercury level in the bottle. The mercury in the receiver was then weighed.

The 8091 g. of mercury (596 cc.) displaced by ethylene at 19.1° and 757.1 mm. pressure corresponds to 0.0247 mole of ethylene.

Analysis of the gas showed the absence of amines and the presence of only traces of formaldehyde. A sample was completely absorbed in bromine water. The ethylene remaining in the system was estimated from the volume and residual pressure and the probable amount dissolved in the liquid mixture of amine, alcohol, formaldehyde, etc., at -77° , to be about 0.0012 mole. The total ethylene formed was thus 0.0259 mole and corresponded to the amount of methylethylamine formed (0.0263 mole) within experimental error.

After removal of the ethylene, dry air was let into the line and an excess of acid added to the trap, while still in the carbon dioxide-ether mixture. The solution of

Fig. 2.

⁹ Pumping was not continued further for fear of pumping over formaldehyde. A correction for the remaining ethylene is made later.

amine hydrochlorides was transferred to a large flask and steam-distilled from acid solution to separate the formaldehyde and amines. The solution was then made alkaline and the amines were distilled into a known volume of standard hydrochloric acid which was then back-titrated. The phosphorus pentoxide from the tube was dissolved in water and treated in a similar manner. There was found in the trap 0.03235 equivalent of volatile base and a negligible quantity in the phosphorus pentoxide.

The amines were distilled from an alkaline solution of the titration mixture into an excess of hydrochloric acid, and the water was evaporated, yielding 3.238 g. of mixed hydrochlorides.

Anal. (Volhard). Found: Cl, 35.25.

This analysis corresponds to 18.5 mole % of diethylmethylamine, and 81.5 mole % of methylethylamine. A weight of salt corresponding to 0.01207 mole of the hydrochloride was treated with benzene sulfonyl chloride to separate the secondary and tertiary amines as described above. Tertiary amine corresponding to 0.00181 mole was obtained. Assuming this to be diethylmethylamine, as in the previous experiment, this corresponds to 15.0 mole % of the decomposition. The value calculated from the chlorine analysis is to be taken as the more accurate, the estimated accuracy being about 1%.

Identification of Residue.—The residue in the weighing bottle weighed 0.8996 g. This was dissolved in water, yielding a solution neutral to phenolphthalein. On boiling, it became alkaline to phenolphthalein. Small quantities of 0.1 *N* sulfuric acid were added and the solution boiled after each addition, until the pink color appeared. Finally, the pink color no longer returned, showing all of the carbon dioxide to have been expelled. The excess of acid was then back-titrated; 0.00101 equivalent of 0.1 *N* sulfuric acid was used.

An excess of sulfuric acid was added and the mixture was steam-distilled, keeping the volume very low, until no more acid came over. The distillate was titrated with 0.1 *N* sodium hydroxide; 31.38 cc. was required. The formic acid was identified by reduction of mercuric chloride; found, 0.00101 equivalent of bicarbonate and 0.00314 of formate; total, 0.0042 equiv. of acid. The nitrogen in the residue from which the formic acid had been distilled was determined by the Kjeldahl method; found, 0.0044 equivalent of nitrogen, which agrees with the quantity of acid found within experimental error.

Expt. 3. High-Temperature Decomposition of Ethoxymethyldiethyl-methylammonium Hydroxide.—0.0455 equivalent of ethoxymethyldiethyl-methylammonium hydroxide in a solution of about one equivalent per 1000 g. was taken for the decomposition. The material was contained in a 500cc. Kjeldahl flask with glass beads to prevent foaming. The Kjeldahl flask was fitted with a spray trap and condenser, the latter dipping below an excess of 0.1 *N* hydrochloric acid. The flask was heated to 135° by means of a glycerol bath. At this temperature boiling took place. Almost as soon as distillation commenced, decomposition set in, as indicated by a piece of moist red litmus in the condenser turning to blue, and by the odor of formaldehyde in the receiver. The main part of the decomposition was carried out at 140–150°. When three-fourths of the liquid in the flask had disappeared, the decomposition became much more rapid. These observations seem to indicate only a slight decomposition through hydrolysis in the first stage and that the main decomposition took place after the liquid reached a low water content, just as in the low-temperature decomposition.

After the apparatus had reached temperature equilibrium, only two or three bubbles of gas escaped, showing that no permanent gas was formed.

When all of the material had decomposed, water was run into the flask and the amines were swept out by steam. Back-titration of the distillate showed the formation

of 0.03659 equivalent of volatile base.¹⁰ The distillate, after being acidified and steam-distilled, was made alkaline, and the volatile amines were collected in an excess of hydrochloric acid. The solution, after evaporation, yielded 4.61 g. of hydrochloride. Before analysis, the hydrochloride was evaporated with absolute alcohol to remove hydrochloric acid.

Anal. (Volhard). Calcd. for $C_6H_{13}NHCl$: Cl, 28.7. Found: 29.4.

This shows that decomposition took place to yield at least 90% of methyldiethylamine.

Expt. 4. Dehydration of Ethoxymethyldiethyl-methylammonium Hydroxide at -15° .—A quantity of ethoxymethyldiethyl-methylammonium hydroxide solution, prepared as above (equivalent weight, 267, at the decomposition concentration), was placed in a container cooled to -15° and a vacuum below 10^{-3} mm. maintained. After three days, no crystals having appeared, the flask was allowed to come to room temperature, when decomposition took place for a considerable time without pumping. A crystalline hydrate could not be obtained.

Preparation of *iso*Butoxymethyl-trimethylammonium Iodide and Hydroxide.—Dimethylaminomethylisobutyl ether was prepared as described by Robinson and Robinson;² b. p., $127-128.5^\circ$; equivalent wt., 132 (calcd., 131). This compound in 50% ether solution reacts explosively with methyl iodide, at room temperature. A 20% solution of the base in anhydrous ether was cooled in ice, and a 10% excess of methyl iodide in 40% anhydrous ether solution was added, taking care to keep out moist air. A white precipitate formed. When all of the methyl iodide had been added, the solution was removed from the ice and allowed to stand at room temperature for three days. The gelatinous mixture was diluted with dry ether and filtered. The salt was washed with ether and dried; m. p., $110-114^\circ$. (In one sample, melting started at 99° and then, almost immediately, the small amount of liquid resolidified. After further drying of the sample, the same phenomenon was noted.) The substance was crystallized from hot butyl alcohol (1 cc. per g.). The recrystallized product (m. p., $103-110^\circ$), after several crystallizations, had the same melting point. Other alcohols, tried as solvents, gave no better results. The compound is very soluble in water and alcohols.

Anal. (Volhard). (Uncrystallized material.) Subs., 0.3290, 0.2774: 12.56, 10.56 cc. of 0.0958 *N* $AgNO_3$. Calcd. for $C_8H_{20}ONI$: I, 46.50. Found: 46.4, 46.3. (Crystallized material.) Subs., 0.4600, 0.5106: 17.68, 19.66 cc. of 0.0958 *N* $AgNO_3$. Calcd. for $C_8H_{20}ONI$: I, 46.50. Found: 46.7, 46.7.

0.0448 mole of *isobutoxymethyl*-trimethylammonium iodide in 100 cc. of water was shaken with a slight excess of silver oxide until the solution no longer gave a test for iodide ion. The silver iodide was filtered off and the solution evaporated as described for the other quaternary bases. Only a very faint odor of amines was perceived.

About 0.004 equivalent of the base was neutralized with hydrochloric acid and the solution evaporated at room temperature over phosphorus pentoxide in a vacuum. The residue was taken up in absolute alcohol and the calculated quantity of chloroplatinic acid in alcohol was added. The platinum double salt was filtered off and washed with alcohol and ether; decomp. at $229.5-230^\circ$ (heating started at 20°).

Anal. (Ignition). Subs., 0.2776: Pt, 0.0780. Calcd. for $C_{12}H_{40}O_2N_2PtCl_6$: Pt, 27.87. Found: 28.13.

After recrystallizing, a constant decomposition point $231-233^\circ$ was obtained under

¹⁰ Complete decomposition was probably prevented, as in the room-temperature decomposition, by the formation of formic acid from the formaldehyde, according to the equation $2H_2CO \rightarrow HCO_2H + CH_3OH$.

the same conditions. Since the iodide is hard to purify, the decomposition point of the platinum salt may be used to characterize the base.

Anal. (Ignition). Subs., 0.1754: Pt, 0.0490. Calcd.: Pt, 27.87. Found: 27.93.

Expt. 5. Decomposition of *iso*Butoxymethyl-trimethylammonium Hydroxide at Room Temperature.—The remainder of the solution of the base, after evaporation over phosphorus pentoxide until decomposition took place, weighed 7.51 g. and had an equivalent weight of 231; 0.0325 equivalent of base was thus present. (Calcd. for the tetrahydrate, equiv. wt., 235.) The material in a weighing bottle was sealed up in the line already described (Fig. 1), the trap being surrounded by liquid air, and the line evacuated to 1.5 mm. Further evacuation was not possible because, if the decomposition became too vigorous, serious frothing took place. The decomposition continued for seven weeks.

When the decomposition was complete, the liquid air was replaced by a solid carbon dioxide and ether mixture. There was no increase in pressure in the line, showing that no ethylene was formed.

Air was let into the line and the amines were isolated as the pure hydrochlorides, as before; 0.0028 equivalent of base was found in the phosphorus pentoxide and 0.0204 in the trap; total, 0.0232 equivalent. (The rest of the base could be accounted for in the residue.)

Anal. (Volhard). Calcd. for C_3H_9NHCl : Cl, 37.15. Found: 37.10, 37.11.

A platinum double salt prepared from this hydrochloride was recrystallized from hot 67% alcohol. Its decomposition point, starting with the bath at 236°, was 240–241°.¹¹

Anal. (Ignition). Subs., 0.2152: Pt, 0.0794. Calcd. for $(C_3H_9NH)_2PtCl_6$: Pt, 36.96. Found: 36.90.

The decomposition thus yields trimethylamine as the only amine.

Expt. 6. Decomposition of Dimethyldiethylammonium Hydroxide at Room Temperature. Decomposition of Normal Carbonate.—Diethyldimethylammonium hydroxide was decomposed by evaporation of a solution in a vacuum desiccator at room temperature. Ethylene, dimethylethylamine and water were the only products formed.

An attempt was made to obtain a crystalline normal carbonate by the evaporation of an aqueous solution of diethyldimethylammonium carbonate at room temperature. Decomposition took place in the concentrated solution, and when an anhydrous solid eventually formed it proved to be the corresponding bicarbonate. This in turn, upon heating, did not give the normal carbonate, but only ethylene, pure ethyldimethylamine, carbon dioxide and water.¹²

Expt. 7. The Conductivity of Fused Ethoxymethyldiethyl-methylammonium Iodide.—Anticipating a high specific conductivity of the fused material, the cell shown in Fig. 3 was designed and used for the measurements. The distance between the electrodes was approximately 20 cm. and the cross-sectional area 0.1 sq. cm. The bulbs facilitated the filling of the cell, each being fitted with a calcium chloride tube to protect the material from moisture.

¹¹ Knorr [*Ber.*, 22, 184 (1889)] gives the decomposition point of trimethylamine chloroplatinate as 240–245°.

¹² The authors are indebted to Mr. R. D. Fowler for this result.

The conductivities were measured by comparison with corresponding resistances of a 9999ohm resistance box, using a Leeds and Northrup bridge for the comparison. The cell constant was determined by filling the cell with 1 *N* potassium chloride solution and determining the conductivity at 25°.

About 10 g. of recrystallized ethoxymethyldiethyl-methylammonium iodide (m. p., 84°) was placed in one of the bulbs and the cell immersed in an oil thermostat at 110°. When the material had melted it was drawn from one bulb to the other until the portion of the cell between the electrodes was entirely full.

After the material had been in the thermostat for half an hour, the conductivity was measured, and then again after one hour. No change was observed. The minima were poor and could not be improved by capacity adjustments. A lower conductivity than was expected prevented readings being taken in the middle of the bridge. These two factors introduce an uncertainty of about 5% in the measurements.

The conductivity was determined periodically over an interval of 12 hours, and found to remain almost constant. The temperature of the thermostat was then raised by steps to 140°, the conductivity being determined at intermediate temperatures and at 140°, in order to determine the effect of viscosity. On cooling to 110°, the conductivity had only changed slightly from its original value. A test showed that the material had almost completely decomposed.

An experiment showed, however, that no appreciable decomposition took place on keeping the original material at 110° for one hour. Further,

Fig. 3.

TABLE I
CONDUCTIVITY OF THE FUSED SALT^a

No.	Time in thermostat hrs	Temp., °C.	Resistance of cell, ohms
1	0.5	110	19,100
2	1	110	20,400
3	3	110	18,400
4	6	110	18,600
5	18	127	11,000
6	24	135	9,000
7	30	139	7,660
8	60	110	15,300

^a Cell constant = 245.

the fact that the conductivity of the material changed but slightly on standing at 110° shows that the impurities had little effect on the conductivity. The conductivity at 110°, after half an hour, may thus be assumed not in error by more than 10%. The results are given in Table I. From No. 1 we calculate $\kappa_{110^\circ} = 0.0128$ mho. The density of the fused salt at 110° was found to be 1.3615 g./cc. From these data we calculate $\Lambda_{110^\circ} = 2.56$.

Summary

*iso*Butoxymethyl-trimethylammonium iodide and hydroxide have been prepared. The electrical conductivity of fused ethoxymethyldiethyl-methylammonium iodide has been measured at 110°.

The decompositions of ethoxymethyldiethyl-methylammonium hydroxide and *isobutoxymethyl*-trimethylammonium hydroxide, on dehydration of the solution at room temperature, have been studied and compared with those of simple quaternary ammonium hydroxides under the same conditions. Ethoxymethyldiethyl-methylammonium hydroxide yields 18.5 mole % of diethylmethylanine and 81.5 mole % of ethylmethylanine, with a corresponding amount of ethylene; *isobutoxymethyl*-trimethylammonium hydroxide yields only trimethylamine. Above 100° the former base yields only diethylmethylanine, upon decomposition. A mechanism similar to that in the decomposition of the simple quaternary ammonium hydroxides is involved. The theory of such decompositions is discussed.

Attempts to prepare crystalline hydrates and anhydrous forms of the above hydroxides failed.

EXTRACTION OF MALTASE FROM YEAST¹

BY V. K. KRIEBLE, E. L. SKAU AND E. W. LOVERING

RECEIVED NOVEMBER 12, 1926

PUBLISHED JULY 5, 1927

Some years ago we were anxious to prepare an active maltase solution to repeat the experiments of Hill² on the action of maltase on a strong glucose solution. As we never succeeded in obtaining a very active maltase solution by the methods given by Hill, we decided to learn more about the extraction of maltase.

We were handicapped by not being able to obtain fresh bottom yeast which is richer in maltase than top yeast. We are, however, very much indebted to the Fleischmann Yeast Company for supplying us at all

¹ Read before the Organic Section of the American Chemical Society in April, 1924, at Washington, D. C.

² Hill, *J. Chem. Soc.*, 73, 634 (1898).

times with their baking yeast, a top yeast—in fact, without their assistance this research would have been impossible.

We soon learned that the heating and fine grinding recommended by Hill did not assist in the extraction of the enzyme. Further experiments showed that previous investigators had not recognized the marked effect of temperature, hydrogen-ion concentration and time on the rates of extraction. Neither had the difference between the rates of extraction from fresh yeast and dried yeast been recognized. When full allowance is made for these factors, many of the contradictory statements in the literature in regard to the content and extraction of maltase from fresh and dry yeast become intelligible.

Experimental Part

Preparation of the Yeast.—The pressed yeast consisting of pure yeast cells and containing about 70% of water was either extracted directly or else dried by the following method. The yeast was forced through a 40- or 60-mesh sieve with a pestle and the resulting threads of yeast were spread on glass plates in front of an electric fan operated at a moderate speed for 18 to 24 hours. The yeast at this stage is crisp and brittle and varies in color from light yellow to brown. It was then ground to a powder and put in a vacuum desiccator over phosphorus pentoxide until constant in weight. Yeast dried in this fashion retained its original maltase activity even after nine months.

Extraction of the Yeast.—Three extraction media were used, namely, 4.6 g. of disodium phosphate, $\text{Na}_2\text{HPO}_4 \cdot 2\text{H}_2\text{O}$, 2 g. of magnesium carbonate and 4.6 g. of $\text{Na}_2\text{HPO}_4 \cdot 2\text{H}_2\text{O} + 6$ cc. of *N* sodium hydroxide solution for 80 cc. of solution in each case. These media gave a *PH*, after the yeast was added, of 8.3 to 8.5, 10 to 10.5 and 11.5 to 12, respectively. In each case, the yeast was ground in a mortar with some water and the substance to be used for extraction. It was then rinsed into a flask and diluted to make 80 cc.; 1 cc. of toluene was added and the flask put into a thermostat. At intervals the flask was thoroughly shaken and a sample removed.³

³ Some experiments were carried out to determine the effect of shaking the yeast in the extraction medium in a shaking machine operated at a slow rate. We used dry yeast and a solution of disodium phosphate for extraction. A parallel set of experiments was carried out where the flasks containing the yeast and phosphate solution were hung in the same thermostats with the following results.

Time of extraction, hrs.	$\frac{3}{4}$	$1\frac{1}{2}$	$2\frac{1}{4}$	3	4	26
Standing	0.42	0.56	0.67	0.67	0.84	0.71
Shaking	.43	.56	.65	.72	.78	.62

Shaking, therefore, does not appear to help very much and, in fact, is somewhat harmful if continued for a number of hours. The values given above, as well as in all other tables, represent decrease in rotation in degrees on a 2% maltase solution determined as described later.

The rapid and complete removal of the cells from the extract proved somewhat difficult. We tried at first to filter through a Büchner funnel and then through a Mandler filter. This is essentially Hill's method and removes the cells but requires large amounts of extract and a good many filter candles. It was found that filtering through a filter plate covered with a dense damp paper worked equally well. Occasionally, the filtrate had to be filtered a second time. By this method both the time of filtration and the amount of media necessary were cut down. The following table gives a comparison of the two methods.

	A	B	C	D
Plate filtration	0 42	0 56	0 71	1 31
Mandler filtration	.42	58	.69	1.25

Plate filtration was used in nearly all of the experiments reported. The only difficulty encountered was in the final stages of autolysis when the filter clogged badly, thus delaying the filtration.

Later on, we had the use of a large centrifuge and carried out a few experiments using the same yeast, extraction medium, temperature and time of extraction, but freed half of the extract from cells by the centrifuge and the rest by the method already described, with the following results.

Time of extraction, hrs	14	17 5	19 5	26
Centrifuge	0 92	0 96	0 94	0 62
Usual filtration	.91	93	.86	63

The centrifuge does not remove all the yeast cells, but apparently the few that are left have small influence so far as the apparent maltase hydrolysis is concerned.

The Activity of the Extract.— A definite amount of the filtrate, which was always slightly alkaline, was neutralized to litmus with a 1% solution of potassium dihydrogen phosphate. One cc. of this neutralized extract was added to 20 cc. of either a 2 or 5% solution of maltase hydrate, buffered with phosphates to a P_H of -6.5 to -6.7 , previously warmed to 30° . The hydrolysis was allowed to continue for 40 minutes at that temperature. Ten drops of glacial acetic acid were then added to stop the action, and one cc. of aluminum cream to aid in filtration. The volume was made up to 25 cc. and the solution immediately filtered. The extent of the hydrolysis was determined polarimetrically, using a 2-dcm. tube. Blanks were run in all cases.

As just stated, 1 cc. of the neutralized extract was used for hydrolysis but all the results in the following curves have been corrected for 1 cc. of the unneutralized extract which corresponds to the maltase taken from 0.1 g. of dry yeast. In making this correction, which was small, it was assumed that the amount of hydrolysis was directly proportional to the

amount of enzyme present—a rule found to hold for small changes in enzyme concentration when the amount of substrate is large.⁴ The ordinates on all of the following curves represent the decrease in rotation of a maltase solution caused by the enzyme extracted from 0.1 g. of yeast when it was allowed to act on the sugar solution for 40 minutes at 30°.

Effect of Temperature on the Extraction of Maltase from Dry Yeast.—

Fig. 1 represents what happens when dry yeast is extracted with sodium phosphate at various temperatures. It is obvious that the rate of extracting the enzyme from the cell increases with temperature. The amount of active enzyme in the extraction medium reaches a maximum, different at each temperature, and then falls off. Apparently, the best conditions for its extraction are not the best for its preservation. So long as the rate of extraction of maltase exceeds the rate of inactivation,

Fig. 1.— Na_2HPO_4 extraction of dry yeast at various temperatures.

the activity increases but when the rates are reversed, the activity falls. It is much easier to obtain a strong maltase solution at a lower temperature as the destruction is slower; furthermore, it is easier to stop extraction at the maximum activity. Similar results were obtained with the other two extraction media.

The Effect of the Hydrogen-Ion Concentration on the Extraction of Maltase from Dry Yeast.—Hill² first pointed out that associated with the autolysis of the yeast cell and the extraction of the maltase, there is a production of acidity in the extraction medium. This has also been observed by Emmerling, Willstätter and others. Most of these investigators neutralized this acid with a solution of sodium hydroxide or ammonium hydroxide or else added a buffer to take care of it. No one, however, has made a systematic study of the effect of the reaction of the medium on the extraction. Fig. 2 gives the activity of maltase obtained

⁴ Bayliss, "The Nature of Enzyme Action," Longmans, Green and Co., London, 1919, 4th ed., p. 107.

at 30° by three different extraction media, having a hydrogen-ion concentration varying from 8.3 to 12. Similar results were obtained at other temperatures. It is obvious that one needs a buffer near neutrality for obtaining the most active extract.

Fig. 2.—30° extraction of dry yeast at various P_H values

The Effect of Hydrogen Ion, Temperature and Time on the Extraction of Maltase from Fresh Yeast.—Figs. 3, 4 and 5 show what happens when the extraction medium and temperature are varied, using fresh yeast. These experiments were all carried out on the same sample

Fig 3.— Na_2HPO_4 extraction of fresh yeast at various temperatures.

of yeast. The extraction in all cases is very much slower with fresh yeast than with dry yeast, as the time scale is different in Figs. 3, 4 and 5 from that used in Figs. 1 and 2. It is apparent that the hydrogen-ion concentration in the extraction medium is not nearly so important with fresh yeast as it is with dry yeast, as the maximum activity observed for a

given temperature is almost the same for the three hydrogen-ion concentrations studied. With dry yeast there was in some cases a four-fold difference. The effect of the temperature at which the extractions are made is also different between the fresh and the dry yeast; 15° seems to be the best for the dry yeast, whereas 30 or 35° is somewhat more

Fig. 4.— MgCO_3 extraction of fresh yeast at various temperatures.

favorable for fresh yeast. Fig. 6 also illustrates this point. This diagram also brings up another very interesting fact, namely, the great difference in samples of yeast. The greatest activity observed in Fig. 6 is nearly 100% higher than that observed in Fig. 3, a corresponding experiment on another sample. We found even greater differences at times between

Fig. 5.— $\text{Na}_2\text{HPO}_4 + \text{NaOH}$ extraction of fresh yeast at various temperatures.

samples which appeared to be perfectly fresh. Whether this is due to the age of the cells, the time interval during shipment, or to the media in which it was grown we are unable to say. It is not due to experimental error, for the results could be checked with the same sample of yeast within a few hundredths of a degree on the polariscope.

Willstätter,⁵ describes a method to determine the amount of maltase

⁵ Willstätter, *Z. physiol Chem*, 111, 157 (1920).

in yeast quantitatively. We followed the method as given and found that the extract which corresponds with 0.256 g. of dry yeast caused a decrease of 0.64° in a 5% buffered solution of maltose hydrate. A part of this same sample of yeast was dried and extracted with disodium phosphate as already described. At the maximum of the extraction curve, 0.1 g. of dry yeast caused a decrease of 0.84° in a 5% buffered solution of maltase hydrate. As the maximum point on our curve can hardly represent the total amount of maltase present, it would appear that Willstätter's method cannot be considered as a quantitative method.

Fig 6.-- Na_2HPO_4 extraction of fresh yeast.

Summary

1. The rate of extraction of maltase from dry yeast varies with temperature. The lower the temperature, the slower the rate.
2. The maximum activity of the maltase extract obtainable from dry yeast varies with hydrogen-ion content of the extraction medium. The more nearly neutral the extraction medium, the more active the extract obtainable.
3. The rate of extraction of maltase from fresh yeast is always slower than from dry yeast.

4. The amount of alkali added to the extraction medium is not as important with fresh yeast as with dry yeast.

5. With dry yeast, 15° is a more satisfactory temperature for extraction than 30°, while with fresh yeast the reverse is true.

THE PREPARATION OF β -TRIPHENYLETHYLAMINE. REARRANGEMENT OF β -TRIPHENYLPROPIONHYDROXAMIC ACID

BY LESLIE HELLERMAN

RECEIVED DECEMBER 27, 1926

PUBLISHED JULY 5, 1927

The preparation of β -triphenylethylamine, $(C_6H_5)_3CCH_2NH_2$, was required in one of a series of researches now in progress in this Laboratory on the mechanism of the oxidation of compounds containing the primary amino group. In order to approach the problem of the exact nature of intermediate products formed when a primary amine of the type RCH_2NH_2 , for example, is oxidized (for instance, in alkaline solution by halogen or by alkyl hypohalite) it was considered desirable to start with a substance of such structural properties that the intermediate products of its oxidation might reasonably be anticipated to possess considerable stability. A consideration of the structure of β -triphenylethylamine, where R is the triphenylmethyl group, from this point of view led to the selection of this substance as a decidedly promising starting product for investigation. It is to be noted, moreover, that this amine possesses potentially reactive hydrogen atoms only on the carbon atom adjacent to the amino group.

The synthesis of β -triphenylethylamine was first attempted by Elbs,¹ who reported that the amine resulted when triphenyl acetonitrile, $(C_6H_5)_3CC\equiv N$, was reduced in alcoholic solution with zinc and hydrochloric acid. Elbs gave a description of the compound, assigning a melting point of 116°, and also reported the preparation of the hydrochloride and the chloroplatinate. No melting point was given for the latter substance and no analyses whatsoever were reported. Later Biltz² reported that he was unable to reproduce the work of Elbs. An exhaustive study of the action of zinc upon the nitrile under varying conditions of solution, concentration and acidity failed to produce a method for the preparation of the amine. Biltz found, indeed, that the nitrile was reduced only³

¹ Elbs, *Ber.*, **17**, 700 (1884)

² Biltz, *Ann.*, **296**, 253 (1897)

³ Compare the stability of triphenyl acetonitrile toward hydrolysis, E. and O. Fischer, *Ann.*, **194**, 262 (1878).

by sodium in the presence of alcohol. But here triphenylmethane and hydrocyanic acid were the only products of reduction found in the reaction mixture. No amine was present.

The writer has verified the results reported by Biltz in every particular. Attempts to obtain the desired amine by reduction of triphenyl acetonitrile have resulted in complete failure. Sodium and alcohol have, as reported by Biltz, been found to effect reduction of the nitrile quantitatively to triphenylmethane and hydrocyanic acid.⁴

In view of the failure of reduction methods⁵ to produce β -triphenylethylamine it was considered best to attempt the preparation of the amine by rearrangement of the corresponding halogenamide, $(\text{C}_6\text{H}_5)_3\text{C} \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{NH}(\text{Hal})$, or hydroxamic acid derivative, $(\text{C}_6\text{H}_5)_3\text{C} \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{NHOH}$. For this purpose it was necessary to prepare β -triphenylpropionic acid, $(\text{C}_6\text{H}_5)_3\text{CCH}_2\text{COOH}$, in suitable yield. Henderson's⁶ method, which uses the action of triphenylbromomethane upon diethyl malonate with subsequent hydrolysis and loss of carbon dioxide leads to a pure acid but in unsatisfactory yield. A modification, tried in this work involving the use of cyano-acetic ester in place of malonic ester, did not lead to improved yields. By far the best way to prepare the acid is by the reaction of triphenylcarbinol and malonic acid.⁷ It has been found that the yield of β -triphenylpropionic acid is not quantitative as reported, but is very good in comparison with yields given by other methods. The amide of this acid, $(\text{C}_6\text{H}_5)_3\text{CCCH}_2\text{CONH}_2$, may be prepared by the usual methods. From the amide a derivative possessing the composition of a dichloro-amide is easily obtained. This, however, does not, by the methods used, lead to the desired amine. Nevertheless it is possible to obtain from the amide an impure bromo-amide (probably a mono-bromo-amide). The latter compound, when rearranged in alcoholic solution with sodium ethylate,⁸ yields in solution an intermediate product, probably the urethan, which upon acid hydrolysis gives β -triphenylethylamine. Analyses of the amine and its hydrochloride, chloroplati-

⁴ The latter observation is of theoretical interest. Violent reduction results, as noted, exclusively in the rupture of the carbon-carbon bond; this suggests that triphenyl acetonitrile may be minimally iodized in alcoholic solution into triphenylmethyl ion and cyanide ion.

⁵ A recent paper by Rupe and Gisiger [*Helv. Chim. Acta* [4] 8, 343 (1925)] describes the reduction of triphenyl acetonitrile by means of hydrogen in the presence of catalytic nickel. The results of this experiment were somewhat uncertain since 15 g. of the nitrile yielded only 0.1 to 0.2 g. of a hydrochloride, the melting point of which was stated to be 214° (m. p. of β -triphenylethylamine hydrochloride observed in the present work, $239\text{--}240^\circ$).

⁶ Henderson, *J. Chem. Soc.*, 51, 226 (1887).

⁷ Fosse, *Compt. rend.*, 145, 197 (1907).

⁸ This procedure is based upon that of Lengfeld and Stieglitz, *Am. Chem. J.*, 16, 370 (1894).

nate, benzoyl derivative and ethyl urethan derivative establish the identity of the compound. The melting point of the amine is 132° as compared with 116° reported by Elbs for his product. Curiously, the nitrate of β -triphenylethylamine is rather difficultly soluble in water.

Because of the unsatisfactory yields given by the bromo-amide procedure, it was deemed valuable to study the preparation of the amine starting with the hydroxamic acid derivative. For this purpose the benzoyl derivative of β -triphenylpropionhydroxamic acid, $(\text{C}_6\text{H}_5)_3\text{C} \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{NHOCOC}_6\text{H}_5$, was synthesized. When this substance is dropped upon a hot aqueous solution of alkali it is practically quantitatively rearranged, yielding β -triphenylethylamine and *sym*.-di- β -triphenylethylurea, $[(\text{C}_6\text{H}_5)_3\text{CCH}_2\text{NH}]_2\text{CO}$. The urea is the chief product of the reaction. From it β -triphenylethylamine is easily obtained in good yield by means of hydrolysis under pressure with alcoholic hydrochloric acid. The relationship of the urea to the amine is further established from the observation that the former compound is produced by the action of phosgene upon the amine.

Experimental Part

Preparation of β -Triphenylpropionic Acid

(A) **By Henderson's Method.**⁶—As stated earlier in the paper, the yields obtained by this method (of the order of 5–10%) were inadequate for the preparation of the considerable quantity of acid required for this work.

(B) **By the Condensation of Cyano-ethyl Acetate and Triphenylbromomethane.**—When sodiocyano-ethyl acetate (suspended in either alcohol or ether) was treated with triphenylbromomethane under conditions similar to those described by Henderson for the analogous operation with sodiodiethyl malonate, the ultimate product was found to consist of yellow needles, probably cyanotriphenylmethylethylacetate, $(\text{C}_6\text{H}_5)_3\text{C} \cdot \text{CH}(\text{CN}) \cdot \text{COOC}_2\text{H}_5$, m. p. $215\text{--}216^{\circ}$, in very poor yield. The product resisted hydrolysis with 50% sulfuric acid at the boiling point of the acid. Because of the low yields no further attempts were made to hydrolyze the product and the method was abandoned for the preparation of β -triphenylpropionic acid.

(C) **By the Method of Fosse.**—Since Fosse⁷ does not give detailed directions for his preparation of β -triphenylpropionic acid, the following procedure which was found to give excellent results in this work is submitted.

Triphenylcarbinol, 100 g., is intimately mixed in a round-bottomed flask with malonic acid, 65 g. The mixture is heated in an oil-bath, at first *cautiously* at $140\text{--}150^{\circ}$, and is maintained within that temperature range until the first vigorous evolution of gas has subsided somewhat. The temperature is then brought to 160° and is maintained there for three hours. The melt is transferred to a beaker and treated with an

excess of sodium hydroxide, and about 1.5 liters of water. The mixture is heated in order to hasten solution and unchanged (almost pure) triphenylcarbinol is removed by filtration of the hot mixture. The cooled filtrate is treated with an excess of hydrochloric acid; β -triphenylpropionic acid precipitates,—usually in perfectly pure condition; the yield varies, 65 to 75 g.

β -Triphenylpropionamide, $(C_6H_5)_3CCH_2CONH_2$.—When β -triphenylpropionic acid (1 mole) is treated with pure thionyl chloride (3 moles), reaction readily takes place in the cold. The action is completed by means of heating just below the boiling point. The solution is allowed to cool slowly, when the acid chloride precipitates in beautifully crystalline form. It is removed by filtration and dried in a vacuum over sodium hydroxide. More may be obtained by means of evaporation of the filtrate at room temperature in a vacuum desiccator over sodium hydroxide; yield, excellent; m. p. of crude product, 132° . The crude product is now cautiously added to a well-agitated, concentrated solution of ammonia. The mixture is heated and is allowed to boil for several minutes; it is then cooled and the solid product, after careful trituration with water, is dried and crystallized two or three times from alcohol. The amide crystallizes from alcohol in white, plate-like crystals, sometimes cubical, resembling sodium chloride in form. It is soluble in benzene, acetone and other common organic solvents; m. p., 192° (corr.).

*Anal.*⁹ Subs., 0.3102 N, 12.8 cc. (over 50% KOH; 21° , 749.0 mm.). Calcd. for $C_{21}H_{19}ON$: N, 4.65. Found. 4.63.

N-Dichloro- β -Triphenylpropionamide, $(C_6H_5)_3CCH_2CONCl_2$.—This was obtained in slightly impure form when β -triphenylpropionamide, 4.5 g., was dissolved in 300 cc. of ethyl alcohol, treated at 5° with a concentrated solution of sodium hypochlorite (prepared from a solution of 15 g. of sodium carbonate and the calculated quantity of chlorine at -5°) and to the resulting solution chlorine water (saturated) was added little by little until a permanent precipitate was obtained. It was collected at once, washed with ice-cold chlorine water and dried in a vacuum over phosphorus pentoxide. The crude product melted at 116° ; when purification was attempted by means of crystallization from chloroform and ligroin, the melting point dropped 13° and the active chlorine content decreased 0.6%.

Anal. Subs., 0.1192· 9.36 cc. of 0.1281 N $Na_2S_2O_3$. Calcd. for $C_{21}H_{19}ONCl_2$: Cl, 10.6. Calcd. for $C_{21}H_{17}ONCl_2$: 19.2. Found: 17.9.

When a portion of the dichloro-amide was heated, chlorine was evolved and the cooled product was a "glass" which seemed to contain no definite chemical individual capable of easy isolation. Only a negligible amount of primary amine salt could be obtained in solution by treatment of the "glass" with hot, dil. hydrochloric acid. Treatment of the chloro compound with soda lime or with sodium ethylate in absolute alcohol likewise failed to yield an amine (after treatment of the resulting mixture with acid). The behavior of this dichloro-amide will be investigated more fully at a later date. It is of interest that the dichloro-amide readily oxidizes cold ethyl alcohol to acetaldehyde; chlorine is evolved at the same time and the parent amide is easily obtainable from solution in pure form: $(C_6H_5)_3CCH_2CONCl_2 + CH_3CH_2OH \longrightarrow (C_6H_5)_3CCH_2CONH_2 + CH_3CHO + Cl_2$.

Preparation of an Impure N-Bromo-amide, $(C_6H_5)_3CCH_2CONHBr$ (?).—Because of the insolubility of β -triphenylpropionamide in water it was found not possible to prepare the corresponding N-bromo-amide

⁹ The writer acknowledges with pleasure the generous assistance rendered by Drs. Andrew M. Neff and T. L. McMeekin in connection with some of the analytical work recorded in this paper.

by the usual procedure for this type of compound. The directions which follow were found to give a product which, when subjected to rearrangement by the Lengfeld-Stieglitz method,⁸ led to β -triphenylethylamine. The bromo-amide mixtures from successive preparations based on these directions were by no means uniform, varying in active bromine content from 9.1% to 13.0%; calcd. for $C_{21}H_{18}ONBr$: Br, 21.0.

To 3 g. of β -triphenylpropionamide dissolved in 200 cc. of ethyl alcohol and cooled to 0°, was added a ten-fold excess of potassium hypobromite in concentrated solution (prepared at -5°). Bromine water at 0° was added at once to precipitate the bromo-amide. This was collected, rapidly freed from mother-liquor, washed with cold bromine water and dried in a vacuum over phosphorus pentoxide. The product, a white powder, was found to be very reactive with hydriodic acid and with other reducing agents.

Rearrangement.—The crude bromo-amide was added to a solution of sodium ethylate (prepared from 1.3 g. of sodium) in 50 cc. of dry ethyl alcohol. The solution was boiled for three quarters of an hour, when a test proved that active bromine was absent. The solvent was allowed to evaporate on a water-bath. The residual viscous mass was washed with water, dissolved in a boiling mixture consisting of 200 cc. of alcohol, and 150 cc. of concd. aqueous hydrochloric acid, and the boiling was continued for five hours. The solvents were then allowed to evaporate; the residue was treated with hot water and the mixture filtered. When sodium hydroxide solution was added to the cooled filtrate a white precipitate resulted. This was taken up in ether, recovered by distillation of the ether, treated with a little concd. hydrochloric acid and the acid mixture was evaporated to dryness. The residual white needles were purified by dissolving in absolute alcohol and reprecipitating with dry ether. A mat of finely twined needles resulted, m. p., 239–240°. Analysis indicated that the product was β -triphenylethylamine hydrochloride. The hydrochloride is moderately soluble in alcohol and in water.

Anal. (Volhard) Calcd. for $C_{20}H_{18}NCl$: Cl, 11.4. Found: 11.5.

β -Triphenylethylamine, $(C_6H_5)_3CCH_2NH_2$.—The hydrochloride, prepared as described in the preceding section, is identical with that obtained after rearrangement of the benzoyl derivative of β -triphenylpropionhydroxamic acid (see below). The free amine was prepared directly in pure condition by adding a small excess of concd. ammonia water to an aqueous solution of the hydrochloride. The precipitate which resulted was collected, washed with water and dried. When viewed under the microscope it was found to consist of crystals which may be described simply but inadequately as elongated hexagonal platelets; m. p., 132° (corr.). When the amine is crystallized from ligroin (purified, b. p. 60–80°) the melting point does not change; the crystal form likewise is unchanged. The amine is soluble in hot ligroin, cold ether and benzene, moderately soluble in acetone and ethyl alcohol, and almost insoluble in water. It gives, with chloroform and potassium hydroxide, the carbylamine reaction.

Anal. Subs., 0.0695 N, 3.1 cc. (over 50% KOH; 20°, 755 mm.). Calcd for $C_{20}H_{19}N$: N, 5.1. Found: 5.0.

SALTS OF THE AMINE—The hydrochloride has already been described (see above). The dichromate (?) precipitates when a solution of a soluble dichromate is added to a solution of amine hydrochloride. The nitrate comes down in very characteristic manner when aqueous solutions of the hydrochloride and nitric acid are mixed. Under the microscope the salt is seen to consist of thin, elongated hexagonal plates. The salt may be crystallized from alcohol; decomposition point, 237°. Its solubility in water at 20° is approximately of the order 1:1000. None of the following ions, chlorate, perchlorate, oxalate, sulfate, interferes with the precipitation of the nitrate. Analysis and more complete solubility data will be submitted later.

CHLOROPLATINATE, $[(C_6H_5)_3CCH_2NH_2]_2PtCl_6$.—When a small excess of chloroplatinic acid solution is added to β -triphenylethylamine hydrochloride dissolved in a small volume of absolute alcohol, the chloroplatinate soon precipitates in yellow-orange crystals, which have the appearance of rhomboids under the microscope; m. p., 183° , with decomposition.

Anal. Subs., 0.1598: Pt, 0.0317. Calcd. for $C_{46}H_{40}PtCl_6$: Pt, 20.41. Found: 19.84.

BENZOYL DERIVATIVE, $(C_6H_5)_3CCH_2NHCOC_6H_5$.—The benzoyl derivative is formed when some β -triphenylethylamine hydrochloride in aqueous solution is shaken with a slight excess of benzoyl chloride in the presence of an excess of sodium carbonate. The product, a solid, is washed with water and crystallized from ethyl alcohol (platelets); m. p., 157.0° (corr.).

Anal. (Micro-Kjeldahl).¹⁰ Calcd. for $C_{27}H_{23}ON$: N, 3.7. Found: 3.6, 3.6.

URETHAN, $(C_6H_5)_3CCH_2NHCOOC_2H_5$.—This is formed when some β -triphenylethylamine is shaken with a small excess of ethyl chlorocarbonate in the presence of an excess of sodium carbonate. When all of the chlorocarbonate has been decomposed (with the aid of sodium hydroxide solution, if necessary) the urethan is taken up with ether, dried with sodium sulfate, recovered by evaporation of the ether, and crystallized from ligroin (b. p., $60-80^\circ$); m. p., 94° .

Anal. (Micro-Kjeldahl). Calcd. for $C_{23}H_{23}O_2N$: N, 4.1. Found: 4.2.

Preparation of β -Triphenylpropionhydroxamic Acid, $(C_6H_5)_3CCH_2CONHOH$.¹¹—A solution of 8 g. of crude β -triphenylpropionyl chloride (see section on preparation of β -triphenylpropionamide, above) in 100 cc. of ether is treated with 2.65 g. of sodium carbonate (anhydrous) and 1.75 g. of hydroxylamine hydrochloride. About 7 cc. of water is added and the mixture is shaken violently until all action has ceased (care: carbon dioxide is evolved). The solid product is brought upon a filter and washed with a little ether; it is thoroughly digested with hot water (to remove inorganic impurities), collected, and dried in a vacuum. The product so obtained is almost pure β -triphenylpropionhydroxamic acid; yield, 90%. It may be crystallized from ethyl acetate. The substance melts and decomposes at 182.5° ; it is readily soluble in alcohol, acetone, hot ethyl acetate and hot benzene; it is not soluble in ligroin. It gives, in alcohol solution, the usual color reaction with ferric chloride.

Anal. (Kjeldahl). Calcd. for $C_{31}H_{29}O_2N$: N, 4.42. Found: 4.23.

BENZOYL DERIVATIVE, $(C_6H_5)_3CCH_2CONHOCOC_6H_5$.—To a portion of the hydroxamic acid (the "crude" product may be used) to which has been added a small excess of 5% potassium hydroxide solution, is added slightly more than an equivalent amount of benzoyl chloride. The mixture is shaken vigorously. Suspended solid matter must be maintained in finely divided form or the benzylation will not be complete. When reaction is complete, potassium hydroxide solution is added, if necessary, until the small quantity of benzoic acid which floats near the surface is just dissolved. The product is collected, washed with water, dried and crystallized from alcohol; m. p., 171.5° ; yield, almost quantitative. The substance gives no color reaction with ferric chloride.

Anal. (Kjeldahl). Calcd. for $C_{33}H_{31}O_4N$: N, 3.33. Found: 3.29.

Rearrangement of the Benzoyl Derivative: Preparation of β -Triphenylethylamine.—The uncrystallized benzoyl derivative prepared from 24 g. of β -triphenyl-

¹⁰ Koch and McMeekin, *THIS JOURNAL*, **46**, 2066 (1924).

¹¹ The method is similar to one of those recommended by Jones and his co-workers, *THIS JOURNAL*, **43**, 2430 (1921); **44**, 412 (1922).

propionhydroxamic acid was added slowly in finely divided form to a gently boiling solution of 190 g. of potassium hydroxide in 500 cc. of water contained in a 2-liter flask. A vigorous reaction took place, accompanied by change of the organic substance to a white, caked mass which floated upon the surface. The mixture was refluxed for 40 minutes, diluted somewhat, cooled and filtered. The residue was washed well with water and then stirred with hot hydrochloric acid. The acid mixture was filtered and the residual solid washed with water and dried at 100°. From the filtrate 2.5 g. of β -triphenylethylamine was obtained by the addition of an excess of aqueous ammonia. The amine, after being dried over potassium hydroxide in a vacuum was practically pure, as indicated by its melting point. Its identity with the product previously obtained by rearrangement of the bromo-amide derivative was further established by conversion to the hydrochloride and the benzoyl derivative.

Analysis and the properties of the residual solid (from the acid treatment; see above) indicated that it was sym.-di- β -triphenylethyl-urea, $[(C_6H_5)_2CCH_2NH]_2CO$. The yield of crude urea was practically that calculated; m. p., 216–218°. When twice crystallized from alcohol the substance was pure and consisted of clumps of long, slender needles; m. p., 218.5–219°. It readily dissolves in benzene from which it may be precipitated by the addition of ligroin. The urea is completely converted to the parent amine by the procedure outlined in the following section.

Anal. Calcd. for $C_{41}H_{36}ON_2$: N, 4.90. Found (Kjeldahl): 4.84, 4.97; (Micro-Kjeldahl) 5.0, 5.0.

Hydrolysis of the Urea.—In sealed Pyrex "bomb" tubes (length, about 58 cm.; internal diameter, 1.7 cm.) the urea (5 g.) is heated with a mixture of 10 cc. of hydrochloric acid (d., 1.18–1.19) and 10 cc. of ethanol (95%) for 12 hours at 150°. The mixture thus obtained is concentrated to remove alcohol, diluted with water and filtered. To the filtrate ammonia is carefully added. Just beyond the "neutral point" a small amount of slightly colored matter precipitates. This is almost pure β -triphenylethylamine. An excess of ammonia is then added; the amine precipitates as a white solid in practically pure form. It is collected and dried. For complete purification it is dissolved in dry ether and the solution is treated with hydrogen chloride. The precipitate is collected, washed with ether and dried. The salt is dissolved in water and ammonia is then added to precipitate the amine.

Formation of the Urea from the Amine.—Some β -triphenylethylamine was treated with an excess of a solution of phosgene in toluene. Reaction was completed and the excess of phosgene removed on the water-bath. Slightly more than the same amount of amine dissolved in benzene was added to the reaction mixture (which presumably contained β -triphenylethylcarbamyl chloride), the solvents were evaporated, and the residual solid was digested with dil. hydrochloric acid to remove the excess of amine. The white solid obtained by filtration of the acid mixture was washed well and dried. Its melting point was 218° and was not lowered by admixture with some di- β -triphenylethyl-urea obtained from rearrangement of the hydroxamic acid derivative.

Summary

1. The synthesis of β -triphenylethylamine has been accomplished by the rearrangement of the benzoyl derivative of β -triphenylpropionhydroxamic acid and also by the rearrangement of an N-bromo derivative of β -triphenylpropionamide. The properties of the amine and those of several derivatives have been described; the properties of the amine and its derivatives have been found to differ from those set forth by Elbs, who stated that he prepared the substance by the reduction of triphenyl-

aceto nitrile, a procedure which could not be confirmed in the present work.

2. Among other new compounds described in this work are β -triphenylpropionamide, β -triphenylpropionhydroxamic acid and its benzoyl derivative, and *sym.*-di- β -triphenylethyl-urea.

3. Detailed directions for the preparation of β -triphenylpropionic acid by the method of Fosse are submitted.

THE OXIDATION OF COMPOUNDS POSSESSING THE PRIMARY AMINO GROUP. I. DIPHENYLMETHYLAMINE

BY LESLIE HELLERMAN AND AGNES GRAHAM SANDERS¹

RECEIVED DECEMBER 27, 1926

PUBLISHED JULY 5, 1927

The mechanism of oxidation of compounds possessing an amino group linked to a primary or secondary carbon atom (RCH_2NH_2 ; $\text{RR}'\text{CHNH}_2$) is a problem of considerable interest to organic chemists, and is also of importance in biological chemistry, particularly in connection with the important question of the oxidation of amino acids. Because of the electronic relationship of amino derivatives to hydroxylated compounds,² it has seemed interesting to inquire to what extent oxidation of amino compounds may, in general, produce substances of the types (that is, aldehydes and ketones as the ultimate products) which are obtained when the corresponding hydroxy derivatives are oxidized. From a theoretical point of view, the question of intermediate compounds formed during the course of an oxidation reaction is of additional importance.

Considerable work is recorded³ in which amino derivatives of types (1) RCH_2NH_2 , (2) $\text{RR}'\text{CHNH}_2$ and (3) $\text{RR}'\text{R}''\text{CNH}_2$ have been subjected to oxidation with agents related to hydrogen peroxide. Bases of the

¹ This preliminary paper is an abstract of part of a dissertation submitted to the University of Chicago by Agnes Graham Sanders, in partial fulfilment of the requirements for the degree of Master of Science, August, 1925. Presented before the Virginia Section of the American Chemical Society, April, 1926.

or $\text{RCH}_2 : \ddot{\text{O}} : \text{H}$. The valence sign $-$ as used here indicates the relative polarity of an atom resulting from the approach of a valence electron pair $:$, and the sign $+$ the corresponding polarity of the other atom held by the doublet bond.

tertiary type (Type 3 and the anilines) yield hydroxylamino derivatives in the first stage of oxidation. Hydroxylamines are undoubtedly also first formed when bases of Types 1 and 2 are oxidized, but in either of these cases the adjacent carbon atom is so readily attacked that the product of the second oxidation stage, an oxime, is the first which may be isolated. For example, $RR'CHNH_2 \rightarrow RR'CHNHOH \rightarrow RR'C=NOH$. The formation of the hydroxylamino derivative may be considered, in a sense, an oxidation of the nitrogen atom. The second step, which leads to the oxidation of the carbon atom linked to nitrogen, involves from the point of view of this paper the more fundamental change. The more active amines of Types 1 and 2 may yield a variety of products; an aldoxime, $RCH:NOH$, for example, which appears from oxidation of RCH_2NH_2 may evidently be further oxidized to the hydroxamic acid stage, since the aldehydo carbon atom still possesses a readily oxidizable position.⁴

Controlled oxidations of amines where the oxidizing agents were other than of the peroxide type have also been reported. Thus, uramil is oxidized to alloxan with great ease by the action of chlorine.^{5a, 6} Benzylamine is largely converted to benzaldehyde by the action of potassium permanganate.^{5b} The same amine, when oxidized with bromine in the presence of sodium ethylate in anhydrous alcoholic solution, yields a gummy product which may be completely hydrolyzed to benzaldehyde and benzonitrile.⁷ Aldehydes have been obtained by the action of oxygen in the presence of copper upon amino compounds.^{5c} Limitations of space prevent detailed discussion of these and other interesting examples.

In the present work, it seemed interesting to inquire what would be the ultimate product of oxidation when a substituted methylamine of high molecular weight is oxidized by bromine in the presence of sodium ethylate in anhydrous alcoholic solution. The amine selected for study was diphenylmethethylamine, $(C_6H_5)_2CHNH_2$.⁸ Bromine was chosen as the

⁴ According to the theory of Stieglitz, aldehydes and their addition products possess "exposed" electrons (readily lost to oxidizing agents) on the aldehydo carbon atom due chiefly to the labile character of the hydrogen atom. Compare Stieglitz, *THIS JOURNAL*, **44**, 1308 (1922); "Qualitative Chemical Analysis," The Century Co., New York, 1911, vol. 1, p. 291.

⁷ Hellerman, unpublished work.

⁸ Since the completion of this work and the writing of the paper Goldschmidt and Beuschel have reported [*Ann.*, **447**, 197 (1926)] the results of work on the oxidation of the same compound with permanganate in absolute acetone solution, the product of oxidation being iminobenzophenone. (Compare results reported in the present work.) These workers assume that the amine is "dehydrogenated" by the oxidizing agent, the resulting intermediate product, $(C_6H_5)_2CH.N<$, transforming itself to the imino compound.

oxidizing agent because it was considered that if the formation of a bromo-amine, $R_2CHNHBBr$, should constitute the first step in the oxidation series, we should have initially a situation comparable⁹ to that which obtains when amines are oxidized to oximes by means of Caro's acid. This distinction must, however, be noted: the hydroxylamines are *much more stable substances* than the bromo-amine derivatives. Anhydrous alcohol was selected as the reaction medium in order that hydrolysis of the bromo-amine derivative, if formed intermediately, might be practically entirely prevented.

As recorded in the experimental section, benzophenone in excellent yield was the ultimate product of the oxidation.^{8a} In order to attempt an elucidation of the nature of the change, it was postulated that the assumed initial product of reaction—the monobromo derivative of the amine, $(C_6H_5)_2CH.NHBBr$ —rearranges or undergoes intramolecular oxidation-reduction, yielding iminobenzophenone according to the equation $(C_6H_5)_2CH.NHBBr + NaOC_2H_5 \rightarrow (C_6H_5)_2C=NH + NaBr + C_2H_5OH$. This imine has been well described;¹⁰ water hydrolyzes it promptly to benzophenone and ammonia. This hydrolysis would constitute the final step in the assumed series of reactions leading from diphenylmethylamine to benzophenone.

In order to ascertain if such an hypothesis of reaction mechanism could be justified experimentally, the behavior of N-chlorodiphenylmethylamine, $(C_6H_5)_2CHNHCl$, in the presence of sodium ethylate in anhydrous alcoholic solution was observed. The N-chloro compound was used because N-chloro-amines stand close to N-bromo-amines chemically and are more easily synthesized than the latter. Its preparation was accomplished by treatment of a solution of the amine hydrochloride with a *neutral* solution of an equimolecular quantity of sodium hypochlorite. This chloro-amine was, in fact, found to resolve itself with great ease, under the conditions of experiment, into iminobenzophenone.

While it would appear undesirable to become committed at the present time to any complete interpretation of such a reaction, the change undoubtedly is related essentially to this fundamental fact: the carbon atom has become oxidized at the expense, ultimately, of the "positive" halogen atom, which has become reduced to halide ion. Such an intramolecular change might, for example, take place very much in the manner of the Hofmann rearrangement.¹¹ In terms of the more recent practices

⁹ Compare the many well-known chemical characteristics manifested in common by hydroxylamino derivatives, $RNHOH$, and halogeno-amines, $RNHX$.

¹¹ Hofmann, *Ber.*, **14**, 2725 (1881). The formulation which follows is intimately related to the general theories of molecular rearrangements which have been advanced by Stieglitz and his collaborators. See *THIS JOURNAL*, **36**, 272 (1914); **38**, 2046 (1916) for references to the literature. Compare also Jones, *Am. Chem. J.*, **50**, 440 (1913).

of polarity expression we should have

Briefly stated, in the presence of the base sodium ethylate, $\text{H} + \text{Cl}-$ is removed from the nitrogen atom in compound I, the nitrogen atom being at the same time oxidized by virtue of the removal of an electron pair by $\text{Cl}:$. The unstable univalent nitrogen derivative II results (intermediately). The nitrogen atom in II now completes its octet by attracting $:\text{H}$ from the carbon atom. The loss of $:\text{H}$ by the carbon atom involves the oxidation of the latter and the whole process results in the formation of iminobenzophenone (III).

In spite of the significant result here obtained for the intramolecular oxidation-reduction of the chloro-amine derivative, it is not to be concluded that *direct* oxidation of amines of Types $\text{RR}'\text{CHNH}_2$ and RCH_2NH_2 with halogens or other oxidizing agents necessarily follows exclusively such a course as has been suggested. *Direct attack* at the carbon atom vicinal to the amino group is by no means excluded. Such a path must, indeed, be especially considered when such activating groups as phenyl (as in benzylamine and in the case under present study) or carbonyl (as in the case of uramil) are carried by the vicinal carbon atom; under such circumstances we should have characteristic labilization of hydrogen atoms carried by the carbon atom and the susceptibility of the latter to oxidation would be markedly enhanced.⁴ The subject will be discussed in greater detail in a later paper which will describe further work on the oxidation of amines of the type $\text{RR}'\text{CHNH}_2$, and of the secondary amines. Work is being continued also on substances of the type RCH_2NH_2 , particularly β -diphenylethylamine and β -triphenylethylamine, $(\text{C}_6\text{H}_5)_3\text{CCH}_2\text{NH}_2$,¹² and on the oxidative mechanism of the α -amino acids, $\text{RCHNH}_2 \cdot \text{COOH}$.

Experimental Part

1. **Oxidation of Diphenylmethylamine.**—Diphenylmethylamine hydrochloride¹³ (5 g), dissolved in 50 cc. of anhydrous alcohol,¹⁴ was treated with an alcoholic solution of 3

¹² Hellerman, *THIS JOURNAL*, 49, 1735 (1927).

¹³ The melting point assigned to this compound in the literature [Leuckart and Bach, *Ber*, 19, 2130 (1886)] is 270° . It was found in the present work that the hydrochloride had not melted at 293° .

¹⁴ Prepared from commercial absolute alcohol by prolonged treatment with lime and careful distillation, care to prevent the introduction of moisture being exercised both in the preparation and storing of the alcohol.

equivalents of sodium ethylate, prepared by treatment of 1.57 g. of sodium with 50 cc. of anhydrous alcohol. With constant shaking, one equivalent of bromine (3.64 g.) was then quickly added; sodium halides precipitated at once. After the reaction mixture had been gently refluxed for half an hour, a test with hydriodic acid for active halogen failed, and the reaction was then considered complete. The solution was slightly acidified with dil. sulfuric acid, and the alcohol was removed by distillation with steam. The reaction product separated from the residual aqueous solution as a light yellow oil. This was extracted with ether and the ethereal extract dried. After evaporation of the ether an oil remained which, when cooled, promptly solidified to a mass of slightly colored, radiating prismatic crystals. The melting point was found to be 47° and was not depressed when the material was mixed with some known benzophenone. The identity of the product as benzophenone was thus established. Of the product, 2.72 g. was obtained (yield, 66%).¹⁵

2. Preparation of *N*-Monochlorodiphenylmethylamine, $(C_6H_5)_2CHNHCl$.—This compound was prepared by the action of the calculated amount of sodium hypochlorite upon a solution of diphenylmethylamine hydrochloride. An alkaline solution of sodium hypochlorite was prepared in the usual way by means of passing chlorine gas into an excess of sodium hydroxide solution at 0° . The active chlorine content of this solution was determined in the usual manner. The solution was analyzed for excess alkalinity by the procedure of Berg.¹⁶ Before use it was titrated for active chlorine, and the required quantity was then treated at 0° , as described by Berg, with the exact amount of standard acid necessary to neutralize the excess of alkali.

For the preparation of *N*-monochlorodiphenylmethylamine, diphenylmethylamine hydrochloride (5 g.) was dissolved in about 30 cc. of water, and to this was added at 5° a neutral solution of sodium hypochlorite containing exactly one molecule of the hypochlorite for each molecule of the amine salt. The mixture almost immediately became cloudy and very soon a pale yellow solid precipitated. This product was collected on a filter at once, washed with three small portions of cold chlorine water, and dried in a vacuum over phosphorus pentoxide. The substance was found to possess the properties characteristic of chloro-amine derivatives. The yield was almost quantitative.

Anal. Calcd for $C_{13}H_{11}NCl_2$: Cl, 28.15. Calcd. for $C_{13}H_{12}NCl$: Cl, 16.3. Found: 15.7, 15.9.

3. Intramolecular Oxidation-Reduction of *N*-Monochlorodiphenylmethylamine.—The chloro-amine (5 g.) was dissolved in 30 cc. of anhydrous alcohol and treated with an equimolecular quantity of sodium ethylate prepared by treatment of 0.52 g. of sodium with 50 cc. of anhydrous alcohol. The mixture was vigorously shaken. Precipitation of a solid (sodium chloride) began at once with the evolution of heat. The mixture was gently refluxed for five minutes. A test at this point for active halogen failed, and the reaction was considered complete. Care to prevent the introduction of moisture was exercised throughout the entire experiment. The alcohol was removed by distillation under reduced pressure (20 mm.). The residue consisted of a mixture of sodium chloride with a quantity of a yellow oil. The oil was found to be identical with iminobenzophenone, as proved in the succeeding section.

4. Isolation of Iminobenzophenone Hydrochloride, $(C_6H_5)_2C=NH_2Cl$.—The

¹⁵ When diaryl methylamines are oxidized under the conditions described in this section by either bromine or iodine, iminoketones have been found to be present in the reaction mixtures, easily isolated as hydrochlorides. Experimental details will be submitted later

¹⁶ Berg, *Ann. chim. phys.*, [7] 3, 289 (1894).

residual oil was extracted with anhydrous ether. The imino compound was next isolated in the form of its hydrochloride in the following manner. The ethereal solution was saturated with dry hydrogen chloride. A white precipitate resulted, which was brought upon a filter, washed with absolute ether, and dried in a vacuum in order to remove ether and traces of free hydrogen chloride. That the product was the hydrochloride of iminobenzophenone was indicated by analysis for chlorine by the Volhard method. The yield was 90% of that expected.

Anal. Calcd. for $C_{13}H_{11}NCl$: Cl, 16.30. Found: 16.43.

This analysis would not, of course, differentiate between the hydrochloride of iminobenzophenone and that of diphenylmethylamine, if present. The former compound may, however, be completely differentiated from the latter by its characteristic behavior when hydrolyzed with water.¹⁷ That the product was *completely hydrolyzed to benzophenone* when dissolved in water is demonstrated by the following. Of the hydrochloride, 1.5 g. was dissolved in 25 cc. of water. A clear solution resulted which almost immediately became milky. After several minutes' standing, it was found that droplets of an oil had collected. The reaction product was carefully extracted with ether. The extract was dried, and the ether was evaporated. A light yellow oil remained which crystallized when it was cooled. The melting point of the product was found to be 47.9° and that of a mixture with some benzophenone was also 47.9° . The recorded melting point of benzophenone is 48° . The yield, 1.2 g., was practically quantitative. A test of the aqueous solution after the ether extraction proved that chloride ion and ammonium ion were present.

Merely as an accessory test, some of the iminobenzophenone hydrochloride obtained in this work was added to a solution of hydroxylamine and sodium carbonate, and the mixture was treated in the manner customarily employed for the preparation of benzophenone oxime. An excellent yield of the pure oxime was obtained.

Summary

1. Some aspects of the problem of the mechanism of oxidation of amino derivatives of the types RCH_2NH_2 and $RR'CHNH_2$ are briefly discussed from the point of view of modern concepts of oxidation-reduction.
2. The oxidation of diphenylmethylamine in anhydrous alcoholic solution in the presence of sodium ethylate is shown to yield benzophenone as the chief product.
3. A mechanism of reaction to account for the product obtained and to elucidate the nature of the reaction is postulated; experimental work is presented which is considered, in a measure, to justify the proposed theory.
4. The conversion of N-monochlorodiphenylmethylamine into iminobenzophenone by means of an anhydrous alcoholic solution of sodium ethylate was accomplished.
5. The preparation of N-monochlorodiphenylmethylamine is described.

RESEARCHES ON MERCAPTOTHIAZOLES. I

BY JAN TEPPEMA AND L. B. SEBRELL

RECEIVED JANUARY 13, 1927

PUBLISHED JULY 5, 1927

Introduction

Since the discovery of 2-mercaptobenzothiazole by Hofmann,¹ who prepared this compound from *o*-amidothiophenol and carbon disulfide, further research on this compound and its possible derivatives was desirable when its value as an accelerator of rubber vulcanization was discovered.

The synthesis of 2-mercaptobenzothiazole from aniline, sulfur and carbon disulfide² not only offered a commercial preparation but made it possible to prepare several derivatives, using a substituted aniline according to the same method. This method, however, is limited in its application, as only six substituted 2-mercaptobenzothiazoles could be prepared. Another disadvantage is the necessity of carrying out the reaction in a closed system whereby pressures as high as 1000 lbs. per sq. in. (7.03×10^5 g./sq. cm.) were obtained.

For laboratory use it seemed very desirable to develop a simple method of preparing 2-mercaptobenzothiazole which could be extended to several new derivatives. The present paper outlines a method of preparing 2-mercaptobenzothiazole in one step from *o*-nitrochlorobenzol, a comparatively cheap material. The method is capable of extension to the preparation of other derivatives such as the halogen, amido and carboxyl derivatives from the corresponding *o*-nitrochlorobenzol derivatives. It has been shown by Blanksma³ that *o*-nitrochlorobenzol reacts easily with sodium disulfide to give dinitrodiphenyl disulfide.

Bogert and Snell⁴ have developed a method for the reduction of this disulfide using zinc and acetic acid, resulting in the formation of the zinc salt of *o*-amidothiophenol, from which Bogert and his co-workers have prepared a large number of phenylbenzothiazoles. From the zinc salt of *o*-amidothiophenol the diaminodiphenyl disulfide was obtained by passing air through its ammonia solution. The best yield obtained by Bogert and by ourselves is approximately 65–75%; the isolation of the pure material is tedious and the loss through crystallization large.

It has been found that the alkaline hydrosulfides are efficient reducing agents for dinitrodiphenyl disulfide, giving a good yield of the corresponding diamino compound.

Several examples are described in the literature whereby alkali hydro-

sulfides are used for the reduction of the nitro compounds to the corresponding amino compounds⁵ and usually the reaction can be accomplished in water solution when the final product is soluble in alkali. In our case the reduction scheme is represented by the following reaction.

Instead of alkali hydrosulfides, sodium hydrosulfite, $\text{Na}_2\text{S}_2\text{O}_4$, can be used, either alone in alcohol, or in water solution in the presence of alkali. The third step in the preparation of 2-mercaptobenzothiazole from *o*-nitrochlorobenzol is the interaction of carbon disulfide with *o*-aminothiophenol. Hofmann obtained it by refluxing *o*-aminophenyl mercaptan with carbon disulfide for 12–14 hours. No data about yields are given, so that the reaction was carried out for the same length of time with *o*-diaminodiphenyl disulfide, giving a low yield of 2-mercaptobenzothiazole. Considering the three reaction schemes by which 2-mercaptobenzothiazole is formed from *o*-nitrochlorobenzol,

it occurred to us that these reactions could be accomplished in one step.

It is known that sodium sulfide solutions absorb carbon disulfide, forming trithiocarbonates, which decompose on heating,⁶

so we may assume that also in the case of sodium hydrosulfide we have the reaction,

and as sodium sulfide is always present in a sodium hydrosulfide solution, Reactions 1 and 2 must take place simultaneously.

This shows that carbon disulfide is converted into a water-soluble trithiocarbonate, which will give carbon disulfide in the nascent and more reactive form.

Another factor that facilitates the formation of 2-mercaptobenzothiazole from diaminodiphenyl disulfide is the use of hydrogen sulfide for the formation of sodium hydrosulfide from sodium sulfide throughout the re-

⁵ Teppema, *Rec. trav. chim.*, **42**, 40 (1923).

⁶ Victor Meyer and Jacobson, *Org. Chem.*, I (2), 1367.

action, whereby the free *o*-amino thiophenol will be present instead of the corresponding disulfide. Experiments confirmed this theory.

It was also possible to combine Reaction 1 with 2 and 3. Blanksma⁷ and Wohlfahrt⁸ state that by the action of sodium disulfide on *o*-nitrochlorobenzol, some *o*-chloro-aniline is formed, and the best yield of dinitrodiphenyl disulfide obtained by ourselves did not exceed 75%. Several modifications in the reactions either cut down or did not affect the yield of final product. To eliminate the loss caused by the reducing action of sodium disulfide on an alcoholic solution of *o*-nitrochlorobenzol, the three reactions were carried out in one step from *o*-nitrochlorobenzol, sodium hydrosulfide and carbon disulfide. The result was an 87.5% yield of 2-mercaptobenzothiazole, based on the *o*-nitrochlorobenzol used; m. p. of the crude material, 173–174°. One crystallization from alcohol gave needles; m. p., 177–178°. The combined reactions may be represented as follows.

As already mentioned, substituted 1-chloro-2-nitrobenzol compounds can be used as starting material. The yields are best for the halogen derivatives. The nine following substituted 2-mercaptobenzothiazoles were prepared according to the method described: 5-chloro-2-mercaptobenzothiazole, 5-bromo-2-mercaptobenzothiazole, 2-mercaptobenzothiazole-5-sulfonic acid (sodium salt), 5-amido-2-mercaptobenzothiazole, 7-methyl-2-mercaptobenzothiazole, 5-methyl-2-mercaptobenzothiazole, 2-mercaptobenzothiazole-5-carboxylic acid, 2-mercaptobenzothiazole-4-carboxylic acid and 2-mercapto-5-oxybenzothiazole.

The combined reaction could not be applied in all cases, as will be shown in the Experimental Part.

Attempts to prepare dichloro-substituted 2-mercaptobenzothiazoles from the corresponding nitrotrichlorobenzois failed and the constitution of the resulting compounds is still in doubt.

The melting points given in this work are all uncorrected. However, they were all made with the same thermometer under identical conditions.

Experimental Part

(a) **Alkali Hydrosulfide Reduction. 2-2'-Diaminodiphenyl Disulfide (Reaction 2).**—A mixture of 5 g. of 2,2'-dinitrodiphenyl disulfide, 150 cc. of water and 30 cc of concd. aqueous ammonia was saturated with hydrogen sulfide and then heated under reflux for two hours. To the solution was added another 30 cc. of concd. aqueous ammonia and it was again saturated with hydrogen sulfide. After refluxing for two

⁷ Blanksma, *Rec. trav. chim.*, **28**, 108 (1909).

⁸ Wohlfahrt, *J. prakt. Chem.*, [2] **66**, 553 (1902).

hours more, the solution was acidified with hydrochloric acid and evaporated on a steam-bath until all of the sulfur had coagulated and a clear solution was obtained. The solution was filtered hot and the residue washed with hot water. The filtrate contains the reduction product, mostly in the form of the hydrochloride of the mercaptan. To oxidize this to the disulfide, two methods were applied.

(1) The acid solution was neutralized by a sodium carbonate solution and air was drawn through the solution to oxidize the free mercaptan to the disulfide.

(2) An alcoholic solution of iodine was added to the acid solution until the iodine color remained. The solution was filtered and the filtrate neutralized with sodium carbonate. The yield of the first product of the diamido compound was 3.9 g.; m. p., 75–80°. Redissolving in hydrochloric acid solution, boiling with charcoal and reprecipitating with sodium carbonate gave 3.4 g.; m. p., 80°. According to the literature, the melting point of the *o*-diaminodiphenyl disulfide is 93°. As another purification of the obtained product by redissolving in hydrochloric acid and reprecipitating with sodium carbonate did not raise the melting point, a sulfur analysis was made

Anal. Calcd. for $C_{12}H_{12}N_2S_2$: S, 26.68. Found: 25.81.

Once recrystallized from dilute alcohol the melting point was 87°. Twenty-five g. of crude product gave 20 g. by recrystallization from dilute alcohol.

Instead of ammonium hydrosulfide, sodium hydrosulfide could be used. With the same procedure, 10 g. of *o*-dinitrodiphenyl disulfide gave 7.6 g. of *o*-diaminodiphenyl disulfide. This product was redissolved in hydrochloric acid, charcoal added, and the solution refluxed for two hours. Reprecipitation gave 7.2 g. of *o*-diaminodiphenyl disulfide; m. p., 80–85°. Recrystallization from dilute alcohol gave 5.5 g. of 2,2'-diaminodiphenyl disulfide; m. p., 87°.

(b) **Reduction with Sodium Hydrosulfite.**—A mixture of 10 g. of *o*-dinitrodiphenyl disulfide and 150 cc. of alcohol was boiled under reflux, and to the hot solution 50 g. of sodium hydrosulfite was added in portions, through the condenser. At each addition 5–10 cc. of water was added; total addition time, one hour; total added water, 100 cc. After two hours' more heating the solution was filtered and the residue (inorganic salts) washed with hot alcohol. The filtrate was acidified and evaporated until dry. The residue was treated with hydrochloric acid and filtered hot. A small amount of tar remained on the filter. The filtrate was rather dark colored and was boiled with charcoal for two hours. After filtering and cooling, the solution was neutralized with sodium carbonate; first product, 8 g.; m. p., 70–75°. Once reprecipitated 7 g. was obtained. Five g. of *o*-diaminodiphenyl disulfide was obtained by recrystallization from dilute alcohol; m. p., 87°.

The reduction of the *o*-dinitrodiphenyl disulfide could also be accomplished by sodium hydrosulfite in water solution if a small amount of alkali was added to increase the solubility of the final product. The melting points given for the *o*-diaminodiphenyl disulfide, that is, 87°, are lower than those usually given for this compound. However, material of this purity was entirely suitable for use in other reactions described later in this paper. Small samples on further recrystallization showed a melting point of 92–93°, but the loss on crystallization is high.⁴

Reaction of *o*-Diaminodiphenyl Disulfide and Carbon Disulfide (Reaction 3).—Five g. of *o*-diaminodiphenyl disulfide, m. p. 87°, and 30 cc. of carbon disulfide were refluxed for 15 hours and carbon disulfide was evaporated on the water-bath. The residue was acidified with hydrochloric acid and filtered hot.

Neutralization with sodium carbonate gave 3 g. of unchanged *o*-diaminodiphenyl disulfide. The residue on the filter was heated with hot, dilute, aqueous ammonia and filtered. A small amount of black tar (sulfur) was left. Filtrate treated with hydrochloric acid gave 2 g. of mercaptobenzothiazole; yield, 32%.

Reduction with Ammonium Hydrosulfide with Carbon Disulfide Present.—A mixture of 5 g. of *o*-dinitrodiphenyl disulfide, 200 cc. of water and 30 cc. of concd. aqueous ammonia was saturated with hydrogen sulfide previously passed through a wash bottle containing water and carbon disulfide. The solution was boiled under reflux at the same time for two hours. After this, the heating was stopped, 30 cc. of concd. aqueous ammonia was added and hydrogen sulfide again bubbled through until the mixture had cooled to room temperature. The mixture was then refluxed again for two hours.

The dark red solution was acidified and evaporated until the sulfur had coagulated and a clear solution was obtained. The white precipitate was filtered and extracted twice with hot aqueous ammonia. Precipitation with hydrochloric acid gave 5.2 g. of mercaptobenzothiazole; m. p., 176°; yield, 96%. The residue on the filter proved to be pure sulfur; m. p., 118°.

Reduction with Sodium Hydrosulfide in the Presence of Carbon Disulfide.—The procedure followed was the same as in the case of ammonium hydrosulfide. Twenty-five g. of sodium sulfide was used instead of ammonia. The advantage of this method lies in the fact that sodium sulfide is regenerated from the sodium hydrosulfide, while in the case of ammonium hydrosulfide the ammonia escapes, forming crystals of ammonium hydrosulfide in the condenser. The yield of mercaptobenzothiazole was identical with the yield obtained above.

In the case of the sodium hydrosulfite reduction the two reactions could not be combined in water solution. Addition of carbon disulfide to the alcoholic solution with sodium hydrosulfite gave a very small amount of mercaptobenzothiazole after a long time of heating. This fact led to the assumption that the easy way in which carbon disulfide reacts in the sodium hydrosulfide reduction method must be explained by the formation of a water-soluble carbon disulfide compound, which decomposes on heating to give carbon disulfide in the nascent state. This assumption is verified by the following experiments.

(a) Five g. of *o*-diamidodiphenyl disulfide and 30 cc. of carbon disulfide were refluxed for 6.5 hrs. The excess of carbon disulfide was evaporated and the residue treated with hot dil. hydrochloric acid to extract unchanged *o*-diamidodiphenyl disulfide. The residue, a mixture of mercaptobenzothiazole and sulfur, was extracted with hot dil. aqueous ammonia and the extract precipitated with hydrochloric acid; yield, 0.5 g.

(b) Five g. of *o*-diamidodiphenyl disulfide, 50 cc. of water and 9 g. of $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$ were saturated with hydrogen sulfide, the latter previously having been passed through a wash bottle containing water and carbon disulfide. After 6.5 hours' reaction, the solution was cooled and acidified with hydrochloric acid, evaporated until the sulfur had coagulated completely, and filtered hot.

The filtrate did not give a precipitate with sodium carbonate solution, an indication that no unchanged *o*-diamidodiphenyl disulfide remained. The residue on the filter was extracted with hot, dilute, aqueous ammonia and precipitated with hydrochloric acid. Six and one-tenth g. of mercaptobenzothiazole was obtained; yield, 98%.

The difference between Expts. (a) and (b) is that in Expt. (b) both carbon disulfide and *o*-amidothiophenol are formed in the nascent state. In

Expt. (a) the free *o*-aminothiophenol is probably formed as an intermediate product.

After a further study it did not appear that the above experiments were sufficiently conclusive since in Expt. a the disulfide must undergo reduction to the free mercaptan before it can react with carbon disulfide.

To prove further the validity of the previous conclusions the following experiments were carried out.

(c) Five g. of *o*-aminothiophenol was refluxed with 25 cc. of carbon disulfide for six hours. After this the carbon disulfide was evaporated and the residual liquid treated with dil. hydrochloric acid. No residue remained after heating on a water-bath.

It seems, therefore, that *o*-aminothiophenol as such reacts very slowly with carbon disulfide. Hofmann claims that 2-mercaptobenzothiazole is formed after 24 hours' refluxing but does not mention the yield obtained.

(d) Five g. of *o*-aminothiophenol and 2 g. of sodium hydroxide were mixed with 50 cc. of water. Carbon dioxide, which had been saturated with carbon disulfide, was bubbled through the mixture, which was then refluxed for six hours. Acidification gave 6 g. of 2-mercaptobenzothiazole (98%). These experiments show that either *o*-aminothiophenol or carbon disulfide in the nascent state causes a complete reaction within reasonable time.

We are thus unable to say definitely that the success of our new method for making 2-mercaptobenzothiazole is entirely dependent upon the formation of nascent carbon disulfide from sodium trithiocarbonate. However, it may be equally dependent upon the presence of nascent *o*-aminothiophenol formed by the action of hydrogen sulfide on the sodium salt.

Combination Reactions 1, 2 and 3.—A solution of 250 g. of $\text{Na}_2\text{S}\cdot 8\text{H}_2\text{O}$ in 1 liter of water was saturated with hydrogen sulfide, the latter previously having been passed through a wash bottle containing water and carbon disulfide. After complete saturation, 100 g. of *o*-nitrochlorobenzol was added and the mixture refluxed for 20 hours on a sand-bath, while hydrogen sulfide saturated with carbon disulfide was bubbled through the solution. It is essential that in the beginning of the reaction the mixture be not heated too strongly. After the reaction was complete, a dark red solution was obtained. The reaction mixture was steam-distilled and the steam distillate extracted with ether. The ether solution was dried over anhydrous potassium carbonate and gave 8.5 g. of *o*-chloro-aniline; b. p., 207°. If the reaction were not carried out to completion, the *o*-chloro-aniline was mixed with unchanged *o*-chloronitrobenzene. These could be separated by extracting the *o*-chloronitrobenzene from the acid-water mixture. The residual water solution was made alkaline and again ether-extracted.

The alkaline residue of the steam distillation was acidified with hydrochloric acid and evaporated until all of the sulfur had coagulated and a clear solution was obtained.

The precipitate, consisting of sulfur and mercaptobenzothiazole, was twice extracted with warm aqueous ammonia and reprecipitated with hydrochloric acid. The water filtrates were concentrated to regain the water-soluble mercaptobenzothiazole; total yield, 92.5 g., or 87.5%.

A modification of this experiment was made by using alcohol as a solvent instead of water. The yield was only 73.5% and the product darker colored than in the reaction where water was used.

If commercial *o*-nitrochlorobenzol (containing a small amount of the *para* derivative) was used, the yield of 2-mercaptobenzothiazole was 84%. The procedure

outlined above was followed in the synthesis of the derivatives of 2-mercaptobenzothiazoles described in this paper, where reference is made to the general procedure.

5-Chloro-2-mercaptobenzothiazole.—Following the same procedure as described for 2-mercaptobenzothiazole, a yield of 87% of 5-chloro-2-mercaptobenzothiazole was obtained. From 250 g. of $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$ dissolved in 500 cc. of water, hydrogen sulfide, carbon disulfide and 100 g. of 1,4-dichloro-2-nitrobenzol, reacted for 20 hours, 91 g. of 5-chloro-2-mercaptobenzothiazole was obtained.

This compound, not previously mentioned in the literature, has an enormous absorption capacity for water and alcohol when first precipitated from these solutions. The best way to obtain it in a dry state is to press it out in a piece of fine-woven cloth. After drying, it was crystallized from alcohol, giving colorless needles; m. p., 192° .

Anal. Calcd. for $\text{C}_7\text{H}_4\text{NS}_2\text{Cl}$: Cl, 17.60; N, 6.94. Found: Cl, 17.18; N, 6.98.

Pressure Reactions.—If the reaction was carried out under pressure, the time for complete reaction was shortened noticeably, but the highest yield obtained did not exceed 62%.

2-Mercaptobenzothiazole-5-sulfonic Acid (Sodium Salt).—This compound was prepared successfully from 2-nitrobromobenzol-4-sulfonic acid. The reaction scheme is as follows.

The reaction product, consisting of sulfur and the sodium salt of 2-mercaptobenzothiazole-5-sulfonic acid, was extracted with boiling alcohol, leaving most of the sulfur behind.

One hundred g. of 2-nitro-1-bromobenzol-4-sulfonic acid gave 70 g. of small, white needles. This material was purified by crystallizing it twice from boiling water, whereby most of the alcohol-soluble sulfur is left behind.

Anal. Calcd. for $\text{C}_7\text{H}_4\text{O}_2\text{NS}_2\text{Na}$: S, 35.68; N, 5.20; Na, 8.55. Found: S, 35.86; N, 4.82; Na, 8.0.

This compound is quite soluble in water and hot alcohol, insoluble in ether, benzene and chloroform.

Properties.—(a) A solution of the sodium salt of 2-mercaptobenzothiazole-sulfonic acid in alcohol gives a precipitate with iodine, proving its nature as a mercaptan.

In water solution no precipitate is formed by the addition of iodine, showing that the sodium salt of the acid is soluble in water.

(b) A water solution of the sodium salt treated with zinc acetate does not give a precipitate. On evaporation to a smaller volume, the unchanged sodium salt is recovered.

(c) A water solution of the sodium salt treated with a water solution of the equivalent amount of lead acetate gave an instantaneous color change to yellow, which disappeared quickly with the formation of a colorless precipitate.

This was filtered, washed with water and dried.

Anal. Calcd. for $\text{C}_7\text{H}_4\text{O}_2\text{NS}_2\text{Pb}$: Pb, 45.80. Found: Pb, 43.66.

5-Amido-2-mercaptobenzothiazole.—The preparation of this compound from 1-chloro-2,4-dinitrobenzol or 2,4-tetranitrodiphenyl disulfide with sodium hydrosulfide and carbon disulfide was not successful.

Forty-five g. of 1-chloro-2,4-dinitrochlorobenzol, 200 g. of $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$, carbon disulfide, and 500 cc. of water were reacted according to the general procedure for 48 hours. The final dark red solution was steam-distilled and the residue of the steam distillate acidified with dil. acetic acid.

The yellow-brown precipitate was filtered and dried; yield, 35 g.

Anal. (Crude product). Calcd. for $\text{C}_7\text{H}_6\text{N}_2\text{S}_2$: S, 35.2. Found: 38.9.

This crude product could not be crystallized from the common organic solvents. The product was extracted with alcohol leaving a considerable amount of residue. The alcohol solution was treated with bone black. On evaporation of the alcohol a yellow solid was obtained which was crystallized from aniline.

The yield of this material was very small. It proved to be 5-amido-2-mercaptobenzothiazole; m. p., 215° .

Anal. Calcd. for $\text{C}_7\text{H}_6\text{N}_2\text{S}_2$: S, 35.2; N, 15.35. Found: S, 35.40; N, 15.45.

If the crude product was not extracted with alcohol but was dissolved in hot pyridine and left standing for 24 hours, colorless rosetts had separated out. They were filtered and washed first with pyridine and then with ether.

For further purification this compound was once more crystallized from pyridine, as it proved to be insoluble in other solvents tried. It did not melt up to 270° .

Anal. Found: S, 50.60; N, 10.47.

This analysis checks for the following formula: dimercaptobenzodithiazole. Calcd. for $\text{C}_8\text{H}_4\text{N}_2\text{S}_4$: S, 50.00; N, 10.93.

The formation of this compound by the interaction of 2,4-dinitrochlorobenzol, sodium hydrosulfide and carbon disulfide is explained by assuming that the sulfur, formed by the violent reduction of the nitro groups, is introduced in *ortho* position to the nitro group in Position 4. This assumption is justified as it is known that sulfur reacts with certain organic amines to form aryl disulfides.⁹

Since it has already been shown that 5-amido-2-mercaptobenzothiazole cannot be formed by treating 2,4-dinitrochlorobenzol with sodium hydrosulfide and carbon disulfide, an attempt was made to prepare 2,4-diamidothiophenol as an intermediate product.

2,2',4,4'-Tetranitrodiphenyl Disulfide.—One hundred g. of 2,4-dinitro-1-chlorobenzol was dissolved in 1 liter of alcohol and a melt of 65.5 g. of $\text{Na}_2\text{S} \cdot 8\text{H}_2\text{O}$, and 9 g. of sulfur was added in small portions. A violent reaction took place and the 2,4,2',4'-tetranitrodiphenyl disulfide separated. To complete the reaction the mixture was heated under reflux on a sand-bath for three hours.

After cooling, the solution was filtered and the residue washed first with alcohol, then with warm water until free from sodium chloride; yield, 86 g. This compound decomposes at 280° , in agreement with Willgerodt.¹⁰

⁹ Schultz and Beyschlag, *Ber.*, 42, 743 (1909).

¹⁰ Willgerodt, *Ber.*, 17R, 352 (1884).

Reduction of 2,4,2',4'-Tetranitrodiphenyl Disulfide and Formation of 5-Amido-2-mercaptobenzothiazole.—Eighty-six g. of 2,4,2',4'-tetranitrodiphenyl disulfide is mixed with 350 g. of tin, and a mixture of 750 cc. of concd. hydrochloric acid and 750 cc. of water added. The solution is slowly heated on a sand-bath until the reaction is completed. Finally the solution is heated for two more hours to complete the reduction. The solution obtained is diluted with its own volume of hot water and filtered. The filtrate is evaporated to a small volume until crystals separate out and most of the excess of hydrochloric acid is evaporated. It is then diluted with seven times its volume of hot water and the solution de-tinned with hydrogen sulfide. The de-tinned solution is evaporated to a smaller volume and neutralized with sodium hydroxide; 150 g. of $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$ is then added to the cold solution and hydrogen sulfide, previously saturated with carbon disulfide, is bubbled through until saturated. The solution is then heated on a sand-bath under reflux for 20 hours, while hydrogen sulfide, previously saturated with carbon disulfide, is bubbled through.

The solution is acidified with dil. acetic acid and the precipitate filtered off and washed with water. The residue is extracted with warm, aqueous ammonia and re-precipitated with dil. acetic acid.

The precipitate is filtered, washed, dried and finally crystallized from freshly distilled aniline; yield, 38 g. of colorless needles; m. p., 216° .

Anal. Calcd. for $\text{C}_7\text{H}_7\text{N}_2\text{S}_2$: S, 35.2; N, 15.35. Found: S, 35.00; N, 14.97.

7-Methyl-2-mercaptobenzothiazole.—Sebrell and Boord² described the preparation of 3-monomethyl derivatives of 2-mercaptobenzothiazole, respectively, 4-, 5- and 6-methyl-2-mercaptobenzothiazole from the corresponding toluidines. They assume that 5-methyl-2-mercaptobenzothiazole is formed according to the following reaction scheme.

Theoretically, it would be possible for the following reaction to take place simultaneously.

In this case, the compound assigned as 5-methyl-2-mercaptobenzothiazole would be a mixture of 5- and 7-methyl-2-mercaptobenzothiazole.

To investigate this, an attempt was made to prepare 7-methyl-2-mercaptobenzothiazole. This is possible according to the new method of preparing substituted 2-mercaptobenzothiazoles from the corresponding *o*-nitrochlorobenzol compounds.

Commercial *o*-toluidine was purified by distillation and the mixed oxalates were prepared from the distillate separated according to the method of Holleman.¹¹

The preparation of 2-chloro-3-nitrotoluene from acetyl-*o*-toluidine is described by Cohen and Dakin.¹² An improvement of the latter part of the reaction is given by Holleman.¹¹

¹¹ Holleman, *Rec. trav. chim.*, **27**, 458 (1908).

¹² Cohen and Dakin, *J. Chem. Soc.*, **79**, 1127 (1901).

Reaction of 2-Chloro-3-nitrotoluene with Sodium Hydrosulfide and Carbon Disulfide.—Seven g. of 2-chloro-3-nitrotoluene, 30 g. of $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$, and carbon disulfide were reacted according to the general procedure for four hours.

The final light red colored solution was steam-distilled, whereby some oil distilled (2-chloro-3-aminotoluene) and the residue acidified with dil. acetic acid.

The precipitate was filtered, washed with water and treated with warm aqueous ammonia. The sulfur was filtered off and the filtrate acidified with dil. acetic acid. The precipitate of 7-methyl-mercaptobenzothiazole was filtered, washed and dried; m. p. (dry), 176–180°. It was crystallized from aniline and then melted at 184°; yield, 2 g.

Anal. Calcd. for $\text{C}_8\text{H}_7\text{NS}_2$: S, 35.36; N, 7.73. Found: S, 35.75; N, 7.47.

As a by-product in this reaction 2-chloro-3-aminotoluene is formed, analogous to the formation of *o*-chloro-aniline from *o*-nitrochlorobenzol.

5-Methyl-2-mercaptobenzothiazole.—This compound could be prepared from 3-nitro-*p*-chlorotoluene, using *p*-toluidine as the starting material.¹³

Reaction of 3-Nitro-4-chlorotoluene with Sodium Hydrosulfide and Carbon Disulfide.—Five and one-half g. of 3-nitro 4-chlorotoluene, 20 g. of $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$, hydrogen sulfide and carbon disulfide were reacted according to the general scheme. The next procedure was identical with the one described for 7-methyl-2-mercaptobenzothiazole; yield of dried, crude material, 3.2 g. It was crystallized from toluene, giving colorless needles; m. p., 171–173°.

This melting point is higher than indicated by Sebrell and Boord for the same compound prepared from *m*-toluidine. The assumption that their compound was a mixture of 5- and 7-methyl-2-mercaptobenzothiazole seems, therefore, to be justified.

Anal. Calcd. for $\text{C}_8\text{H}_7\text{N}_2\text{S}_2$: S, 35.36; N, 7.73. Found: S, 35.85; N, 7.42.

2-Mercaptobenzothiazole-5-carboxylic Acid.—2-Nitro-4-cyano-1-chlorobenzol was prepared from *p*-chloro-aniline according to Mattaar.¹⁴

The saponification of 2-nitro-4-cyano-1-chlorobenzol was accomplished by dil sulfuric acid (1:1).¹⁵ The yield of 4-chloro-3-nitrobenzoic acid is almost quantitative. 4-Chloro-3-nitrobenzoic acid was treated with sodium hydrosulfide and carbon disulfide according to the general procedure described for previous *o*-chloronitrobenzol compounds.

Ten g. of 4-chloro-3-nitrobenzoic acid, 50 g. of $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$, hydrogen sulfide and carbon disulfide reacted for six hours gave 6 g. of 2-mercaptobenzothiazole-5-carboxylic acid.

After cooling, the solution was acidified with dil. acetic acid and the precipitate filtered, washed and while still wet digested with warm aqueous ammonia. The solution was filtered from undissolved sulfur and the filtrate acidified with dil. acetic acid. The precipitate was filtered and dried; yield, 6 g.

This compound was difficultly soluble in water and cold alcohol and slightly soluble in warm glacial acetic acid.

It was crystallized from glacial acetic acid, giving white needles which did not melt up to 270°.

Anal. Calcd. for $\text{C}_8\text{H}_5\text{O}_2\text{NS}_2$: S, 30.33; N, 6.63. Found: S, 29.88; N, 7.01.

To prove the presence of a carboxyl group this compound was titrated in 50% alcohol-water solution, with 0.1 *N* sodium hydroxide solution, using phenolphthalein as an indicator.

Titration. Calcd. for $\text{C}_8\text{H}_5\text{O}_2\text{NS}_2$: 28.43 cc. Found: 28.40 cc.

¹³ Gattermann, *Ber.*, 18, 2600 (1885).

¹⁵ Claus and Kurz, *J. prakt. Chem.*, [2] 37, 200 (1888).

Attempts to Prepare Dichloro-2-mercaptobenzothiazole.—Attempts were made to prepare dichloro-substituted 2-mercaptobenzothiazoles by the general procedure described above from (1) 1,2,4-trichloro-*o*-nitrobenzol, prepared as described by Lesimple;¹⁶ (2) 2,2'-dinitro-4,5,4',5'-tetrachlorodiphenyl disulfide, obtained from *o*-dichlorobenzol as described by Blanksma.¹⁷

In both cases compounds were obtained which indicated that one chlorine atom was replaced by a mercaptan group. However, the yields of the products were very poor and no effort has been made to clear up their exact structure.

(3) *p*-NITRO-ANILINE.—It was thought that a dichloro-2-mercaptobenzothiazole could be formed from 2,2',4,4'-tetrachloro-6,6'-dinitrodiphenyl disulfide, which is obtained from *p*-nitro-aniline as described by Holleman and Blanksma.¹⁸

Seventy g. of this material, m. p., 190°, and 200 g. of Na₂S·9H₂O dissolved in 500 cc. of water and treated according to the general procedure gave 22 g. of a colorless, amorphous powder.

This material was crystallized from xylene and gave 18.5 g. of colorless needles; m. p., 213°.

Anal. Found: N, 7.12; S, 15.10; Cl, 36.52.

The analysis checks for the formula

and not for the expected compound

We have here a remarkable case where the ring closing of the *o*-amidothiophenol to the thiazole ring is prevented by the other substituents present. Under what conditions the ring closing can occur will be investigated later. As a substituted thiophenol this compound is new in its class.

Summary

A new method for the preparation of 2-mercaptobenzothiazole is described, which is especially suitable for laboratory use. This method was extended to several new derivatives and is especially suitable for the monohalogen derivatives. The general synthesis could not be applied for the dihalogenated 2-mercaptobenzothiazoles.

ACTION OF BENZYLAMINE ON GLUCOSE IN ACETIC ACID SOLUTION. III

By C. N. CAMERON

RECEIVED JANUARY 24, 1927

PUBLISHED JULY 5, 1927

The reaction between amines and glucose is being studied in the hope that it may throw some light on the reaction of amino acids and carbohydrates. Not only do aromatic and aliphatic amines react with carbohydrates, but amino acids do also, and apparently in a similar manner. Thus Irvine and his collaborators have shown that alanine¹ and *o*-aminobenzoic acid² react with glucose in the cold just as aniline does. However, when *o*-aminobenzoic acid is heated with glucose, extensive decomposition occurs and little of the *o*-carboxy-anilide can be isolated. Similarly, it has been shown that when glucose and glycine³ are heated in water solution, cyclic condensation products containing nitrogen are formed. Again, it is found that there is the greatest increase of "humins" nitrogen from dextrose and protein hydrolysates⁴ when the solution is neutral or weakly acid. This shows that glucose may react directly with the amino acids and that this compound may give rise to the humins.

When glucose is allowed to react with amines such as aniline⁵ in the presence of acetic acid, apparently the same type of reaction occurs. First a compound, glucose-anilide, is formed and this in the presence of acid undergoes further changes; glucose-anilide disappears and brown condensation products are formed.

The latter change is still the subject of study, but tentatively the following explanation is offered. It has already been indicated that glucose-anilide in acid solution becomes "reactive." This might be due to the formation of the aldehyde isomer, which then may change to the enol or break down to methyl glyoxal. If the enol does form, then there may be formed nitrogen ring compounds of various types of which the formation of 2,5-ditetroxybutyl-1,4-diphenyl pyrazine is an example.

This would be similar to the formation of 2,5-ditetroxybutyl pyrazine⁶ from fructose and ammonia in methyl alcohol solution.

On the other hand, it was noticed that glucose-benzylamide residues in methyl alcohol containing acetic acid which had been left exposed to the air became colored, and a distinctly quinoline-like odor developed. Hence it was thought that methyl glyoxal or pyruvic acid might be formed from the "reactive" glucose and that one of these and the amine gave rise to the colored product. This would be comparable to the formation of pyrazine derivatives from ammonia and phenyl glyoxal,⁷ or to the production of methyl cinchoninic acid from aniline and pyruvic acid.⁸

It has been found, in fact, that alcoholic solutions of glucose-benzylamide containing acetic acid, in 24 hours gave a test for methyl glyoxal;⁹ also, that solutions of benzylamine, glucose and acetic acid in alcohol soon give the same test, the time varying with the concentration of the reactants. Solutions of benzylamine and glucose did not give the test during the time of observation. As a test which depends upon a change of color of sodium nitroprusside in alkali and in acid is liable to be misleading, an attempt was made to isolate the methyl glyoxal as the osazone. It was found that by adding *p*-nitrophenylhydrazine to solutions of glucose, benzylamine and acetic acid, the corresponding osazone of methyl glyoxal¹⁰ slowly forms and can be identified. Similarly, from acid solutions of glucose-benzylamide in the presence of *p*-nitrophenylhydrazine, the same osazone is formed in small amounts. Apparently, then, one of the products of the action of benzylamine and glucose in the presence of acetic acid is methyl glyoxal and this, of course, may react with the benzylamine to give various nitrogen ring compounds, but whether this is the only mechanism is still an open question.

Experimental Part

Preparation of Glucose-benzylamide.—Ten g. of glucose was dissolved in 200 cc. of hot 95% alcohol and 17.8 g. (3 molecular proportions) of benzylamine added. The reaction mixture was heated for ten minutes at boiling; it was filtered hot and allowed to stand for 48 hours. It was then cooled in ice water and a gelatinous precipitate separated. This was removed by filtration, thoroughly washed with anhydrous ether and dried in a vacuum. This method yielded a slightly yellow substance, m. p. 70–75°, the yields varying from 80–85%. A 3% solution in methyl alcohol gave $\alpha = -0.61$ to -0.52° in 24 hours in a 1-dcm. tube.

Glucose-benzylamide, recrystallized four times from methyl alcohol and anhydrous ether, is a colorless substance with a bitter taste. It is somewhat soluble in water, but solution is slow. Rather easily hydrolyzed, it reduces Fehling's solution on heating. It is quite soluble in cold methyl and in hot ethyl alcohol, but from the latter it separates as a gel on cooling; it is only slightly soluble in ligroin, benzene, ether and ethyl acetate. The pure material melted at 81.5°; a 3% solution in methyl alcohol gave $\alpha = -1.28$ to -0.68° in 24 hours in a 1-dcm. tube, whence $[\alpha]_D^{25} = -22.66^\circ$.

Glucose, Benzylamine and Acetic Acid.—When glucose is allowed to react with benzylamine in ethyl alcohol at room temperature and the reaction is followed by means of the polariscope, it is found (Table I) that during the first six hours the rotation becomes very slightly more positive, then gradually less positive and finally negative. That is, the reaction is of the same type as those previously studied by Irvine.¹¹ When acetic acid is also present, the preliminary lag in the rotation is not apparent; the rotation gradually became negative just as was the case with aniline, glucose and acetic acid.

TABLE I

EFFECT OF ACETIC ACID ON THE REACTION BETWEEN GLUCOSE AND BENZYLAMINE

Effect of Changing the Concentration of Acetic Acid on the Reaction between Glucose and Benzylamine.—As glucose solutions containing benzylamine and acetic acid in a 1:1 proportion were acid to litmus five minutes after mixing, it seemed worth while to study the reaction when the ratio of amine to acid was in other proportions, in an attempt to keep the reaction near the neutral point. The result is shown in Table II.

TABLE II

EFFECT OF CHANGE OF CONCENTRATION OF ACETIC ACID ON THE REACTION BETWEEN
BENZYLAMINE AND GLUCOSE

¹¹ (a) Irvine and Gilmour, *J. Chem. Soc.*, 93, 1429 (1908). (b) Irvine and Nicoll, *ibid.*, 97, 1449 (1910).

The hydrogen-ion concentration was followed approximately by means of indicators. Reaction mixture No. 1 was alkaline to phenolphthalein during 20 days. No. 2 was alkaline on mixing, but gradually the alkalinity diminished until in six hours phenolphthalein was not affected and in two days it became slightly acid to litmus and remained thus for 20 days. On mixing, No. 3 was slightly alkaline, but in 30 minutes it had no effect on phenolphthalein; in three hours it was slightly acid to litmus and remained acid. The fourth solution became faintly acid to litmus 15 minutes after mixing and remained acid thereafter.

It might be pointed out, then, that Reaction 2 (Table II) took place, colored material was produced, it gave the test for methyl glyoxal described later and yet the hydrogen-ion concentration at all times was not far from the neutral point. Curiously also this reaction, slower at first, was most rapid as measured by the change in rotation during a 24-hour period.

Glucose-benzylamide and Acetic Acid.—The colored material produced in glucose, benzylamine and acetic acid solutions is due first (a) to the formation of glucose-benzylamide and then (b) to the action of acetic acid on this compound as indicated by the following.

(a) To an alcohol solution of 3 g. of glucose were added 5.35 g. of benzylamine and 3 g. of acetic acid and the solution was made up to 50 cc. After three days, a large excess of anhydrous ether was added to the ice-cooled reaction mixture and the gelatinous precipitate which separated was removed by filtration. This material was glucose-benzylamide; yield, 0.55 g.; m. p., 80–81°; 0.3422 g. in 25 cc. of methyl alcohol gave $\alpha = -0.30^\circ$ in a 1-dcm. tube, hence $[\alpha]_D^{25} = -21.9^\circ$.

(b) It was found that a 3% solution of glucose-benzylamide in methyl alcohol, in a 1-dcm. tube, gave $\alpha = -1.27^\circ$ in five minutes, -0.69° in 24 hours and -0.64° in 24 days. The solution was colored only a light yellow in 40 days. A comparable solution, containing 0.67 g. of acetic acid in 100 cc. of a 3% solution of glucose-benzylamide in methyl alcohol gave, in a 1-dcm. tube, $\alpha = -0.69^\circ$ in five minutes and -0.42° in six hours. It became light yellow in one day and was red-brown in seven days.

Test for Methyl Glyoxal.—It was found that alcohol solutions of glucose-benzylamide, containing acetic acid and solutions of glucose, benzylamine and acetic acid gave the following test for methyl glyoxal, whereas comparable blanks did not.

To 0.5 cc. of the solution, suspected to contain methyl glyoxal, was added 0.5 cc. of freshly prepared solution of 2% sodium nitroprusside. On the addition of 0.5 cc. of 10% sodium hydroxide the mixture turns red if methyl glyoxal is present. When the reaction mixture is made acid with acetic acid, a violet color is produced. This color, as a rule, persists for some time.

When the test was applied to 3% alcohol solutions of glucose, fructose, glucose-benzylamide, glucose and benzylamine (1, 3 and 6 molecular proportions) during a period of 24 days, the alkaline mixture was yellow; on acidifying with acetic acid, an amber color developed. On the other hand, a 3% solution of glucose-benzylamide in alcohol, containing 0.67 g. of acetic acid (1 molecular proportion) gave a slight test in six hours, a positive test in one day and continued to give it for at least 30 days.

Similarly, alcohol solutions of glucose (3%), benzylamine and acetic acid (1, 3 and 6 molecular proportions, as in Table I) gave a positive test for methyl glyoxal in one day after mixing, and continued positive.

***p*-Nitrophenylosazone of Methyl Glyoxal.**—To 100 cc. of a 48-hour old solution of 3% glucose containing benzylamine and acetic acid (3 molecular proportions), were added 1 g. of *p*-nitrophenylhydrazine and 0.35 cc. of glacial acetic acid. The reaction mixture was shaken until the phenylhydrazine had dissolved and was then filtered from a slight residue. An amorphous precipitate slowly formed and in six days this was removed. The amount was so small that nothing definite could be decided. A further 1 g. of *p*-nitrophenylhydrazine was added, and 40 days after the first addition of phenylhydrazine the precipitate was removed. The precipitate was washed with hot alcohol and dried in a vacuum. It weighed 0.18 g.; m. p., 260–269°, with decomposition. It gave the test for the *p*-nitrophenylosazone of methyl glyoxal.¹⁰ The precipitate was washed with hot 10% sodium carbonate solution, then with water, alcohol and ether. The alkaline filtrate gave no precipitate on acidifying with acetic acid, showing the absence of the *p*-nitrophenylhydrazone of pyruvic acid. The original precipitate was recrystallized from nitrobenzene and toluene; the crimson needles obtained weighed 0.10 g.; m. p., 299–300°. When mixed with the *p*-nitrophenylosazone of methyl glyoxal, the melting point was unchanged. Other samples of a similar material were obtained and analyzed.

Anal. Calcd. for $C_{15}H_{14}N_4O_4$: N, 24.56. Found: 24.62.

In acid solutions of glucose-benzylamide containing *p*-nitrophenylhydrazine, the amorphous precipitate forms only very slowly. Thus in 40 days only 0.08 g. of material was obtained from 100 cc. of a methyl alcohol solution of 3 g. of glucose-benzylamide, 2 g. of *p*-nitrophenylhydrazine and 1.8 g. of acetic acid. This precipitate, when purified, melted at 297–298° and gave the color test for the *p*-nitrophenylosazone of methyl glyoxal.

Glucose-Benzylamide in Water.—It has been found that with glucose, aniline and acetic acid or with glucose-anilide and acetic acid in water solution, a brown precipitate gradually forms and it was thought that glucose-benzylamide would react in a similar manner. Apparently, however, this substance in water hydrolyzes directly to glucose and benzylamine (Table III); the solutions do not yield colored products nor do they give the test for methyl glyoxal.

TABLE III
GLUCOSE-BENZYLAMIDE IN WATER

Glucose-benzylamide, 0.5 g.; water to 50 cc.; tube, 1 dcm.; temp., 20–22°.

Acetic acid Time ^a	None α	0.11 g. (1 mole propn.) α
5 min.	–0.43	+0.10
15 min.	–.42	+ .31
30 min.	–.42	+ .33
1 hour	–.40	+ .34
1 day	–.80	+ .34
2 days	–.23	+ .35
24 days	+ .14	

^a Time was computed from contact of the glucose-benzylamide and water, but with acid present from the time of addition of the acid, five minutes after solution.

Glucose-benzylamide in water slowly hydrolyzed until in 36 days the solution became opalescent due to the separation of benzylamine. During 80 days, no coloration was noted and no test for methyl glyoxal was obtained. With 1 molecular proportion of acetic acid present the glucose-benzylamide quickly hydrolyzed, so that in 30 minutes it was practically complete. (Complete hydrolysis of 0.5 g. of glucose-benzylamide should give a rotation of $+0.35^\circ$.) In 80 days, no color developed and the methyl glyoxal test was negative. Even with a small concentration of acid present, as in the experiment below, in 80 days there was no colored precipitate and no test for methyl glyoxal but the reaction mixture had a slight quinoline-like odor.

To 0.5 g. of glucose-benzylamide in water, 0.028 g. of acetic acid (0.25 molecular proportion) was added and the solution made up to 50 cc. Five minutes after the addition of acid and 15 minutes after contact of the amide and water, the rotation in a 1-dcm. tube was -0.28° , in six days it was -0.08° and in 24 days, -0.20° .

Glucose, Benzylamine and Acetic Acid in Water.—The following experiments indicate that benzylamine and glucose in water react to form glucose-benzylamide. However, with 1 molecular proportion of acetic acid present, no reaction apparently occurs, which would be expected from the action of acid on glucose-benzylamide in water. Apparently acetic acid catalyzes the hydrolysis of glucose-benzylamide to a greater extent than it does the "activation." Then one would expect that with a low concentration of acid, activation might occur and brown products form. This is found to be true.

To a water solution of 1.5 g. of glucose was added 0.89 g. of benzylamine (1 molecular proportion) and 0.5 g. of acetic acid (1 molecular proportion) and the solution was made up to 50 cc. During six days (at $20-21^\circ$) there was no change in rotation and the test for methyl glyoxal was negative. In 80 days, no colored material had formed.

To a water solution of 1.5 g. of glucose was added 0.45 g. of benzylamine (0.5 molecular proportion) and the solution was made up to 50 cc. In six days (at $20-21^\circ$) the rotation in a 1-dcm. tube had changed from -1.51 to -0.40° , but thereafter the reaction mixture became opalescent due to the separation of a small amount of glucose-benzylamide. During 20 days it gave no test for methyl glyoxal and in 80 days no colored precipitate.

A similar glucose solution, containing 0.89 g. of benzylamine (1 molecular proportion) and 0.06 g. of acetic acid (0.0125 molecular proportion) in 50 cc., was cloudy from the start and the rotation could not be read. During 20 days the test for methyl glyoxal was negative but gradually a small amount of brown oil collected and the solution had a nicotine-like odor. After 80 days (at $20-21^\circ$) the oil was extracted with ether, the ether evaporated and the residual oil fused with potassium hydroxide, when a quinoline-like odor was detected. However, the amount of material was too small to ensure any definite conclusions as to its nature.

Summary

It is shown that in alcohol, benzylamine and glucose in the presence of acetic acid react to form glucose-benzylamide and that the latter is then, in part at least, converted into methyl glyoxal. The methyl glyoxal, presumably, reacts with the amine to form nitrogen ring compounds. It is found that the acetic acid catalyzes the reaction between benzylamine and glucose and that even small amounts of acid are effective,

so that the production of the methyl glyoxal may occur in reaction mixtures which are near the neutral point.

In water solutions, glucose does not react with benzylamine in the presence of acetic acid, when the amine and acid are in a one to one ratio but when the amount of acid used is very small, then reaction does occur as in alcohol. Glucose-benzylamide in water solution is hydrolyzed very readily to the constituent compounds, and the formation of methyl glyoxal or nitrogen ring compounds was not apparent under these conditions.

THE MECHANISM OF THE CHANGE OF ISONITRO TO NITRO COMPOUNDS

BY GERALD E. K. BRANCH AND J. JAXON-DEELMAN

RECEIVED FEBRUARY 1, 1927

PUBLISHED JULY 5, 1927

Introduction

It has been shown by Hantzsch¹ that the reversible electrolytic dissociations of nitromethanes are slow enough in both directions to permit the measurement of the rates of change of electrical conductivity when nitromethanes react with bases to form salts or when nitromethanes are formed from their salts by reaction with hydrogen ion. He explained the anomalously slow rates of these homogeneous ionic reactions as due to accompanying changes of structure. The formula RCH_2NO_2 has been accepted as that of the nitromethanes, while the alternative formulas $\text{RCH}=\text{N}\begin{smallmatrix} \text{O} \\ \diagup \quad \diagdown \\ \text{O}^- \end{smallmatrix}$ and $\text{RCH}-\text{N}-\text{O}^-$ have been assigned to the ions. Hantzsch prefers

the latter formula. This theory is supported by the existence of an isomeric but unstable form of phenylnitromethane, which can be obtained from solutions of the salts of phenylnitromethane by rapid precipitation with hydrochloric acid.

Hantzsch's measurements of the rates of these reactions are not sufficiently accurate to show the mechanisms of the changes, although they do indicate that these are somewhat complex. We have, therefore, attempted to elucidate the mechanisms of these reactions through more accurate measurements of the rates.

Phenylnitromethane and nitromethane were chosen as examples of aryl-substituted and purely aliphatic nitromethanes, respectively, both of these substances having previously been used by Hantzsch. *p*-Nitrophenol was chosen as an example of a different type of nitro compound

¹ Hantzsch, *Ber.*, 29, 2251 (1896); 32, 607 (1899).

whose behavior as an acid is presumably also accompanied by a change in structure.

The rates were measured only for the reactions in one direction, that of the formation of the nitro compounds by the combination of the ions. They were carried out at two temperatures in each case, in order to see whether the heats of activation for the reactions were markedly different for these types of nitro compounds.

The conditions under which the experiments were carried out, that is, at low temperatures, in dilute solutions, and without excess of acid, were such that secondary decompositions of the nitro compounds, even of nitromethane, were negligible.

Experimental Part

General Method.-- Solutions containing equivalent amounts of the sodium salt of the nitro compound in question and of hydrochloric acid were mixed. The normality of each solution was 0.01 and equal volumes of the solutions were used, so that after mixing, the resulting solution was 0.005 *N* with respect to both sodium chloride and the isonitro acid. The solvent for all the solutions was a mixture of methyl alcohol and water, containing 500 cc. of the former substance per liter of the solution. These concentrations are such that no substance crystallizes out during the experiment, even at -24° . The same solvent was used to make up both solutions so as to avoid the heating effects due to mixing methyl alcohol and water. The solutions were cooled to the temperature of the thermostat, and then thoroughly mixed. This process was carried out with the minimum removal of the flasks from the thermostat. Blank experiments showed that this could be done without raising the temperature of the solutions more than 0.1° . When mixed, the solution was rapidly sucked into a conductivity cell, which had also been allowed to reach the temperature of the bath. This cell was essentially a U-shaped tube with two bulbs, into one of which platinum plate electrodes were sealed and afterwards platinized. The ends of the tubes were supplied with stopcocks, so that when these were shut no changes of the level of the liquid could occur during the experiment.

Measurements of the conductivity were then made at different times, over a range corresponding to a 100-fold change of concentration of the pseudo nitro compound. The final conductivity was obtained by allowing the solution to stand until all significant changes of conductivity had taken place, and then measuring the conductivity. This measurement was preferred to that obtained by measuring the conductivity of 0.005 *N* sodium chloride solution, as it avoids the errors and delay which occur when a level has to be adjusted to a mark. Further, the use of the final conductivity instead of that of a 0.005 *N* solution of sodium chloride

automatically corrects for any reversibility of the reactions in cases, such as these, in which the reactions are very nearly completed. However, the differences between the final conductivities and that of 0.005 *N* sodium chloride are not greater than those which could be produced by filling the tubes to different levels.

Source of Chemicals.—The phenylnitromethane was prepared by the action of benzyl bromide on silver nitrite. It was purified by precipitating its sodium salt from an ethereal solution of the phenylnitromethane with a solution of sodium methylate in methyl alcohol. The salt was then taken up in water, and the aqueous solution was freed from practically neutral substances, for example, benzyl alcohol, by washing it with ether. The phenylnitromethane was precipitated from the aqueous solution of its salt with carbon dioxide. It was then fractionally distilled in a vacuum.²

The nitromethane, a Kahlbaum preparation, was purified by fractional distillation. A fraction which distilled between 100.5 and 101.5° was used.

The *p*-nitrophenol was also a Kahlbaum preparation. It was purified by crystallization from water; *m. p.*, 114°.

The standard solutions of the salts of the nitro compounds were prepared by dissolving weighed quantities of the nitro compounds in 0.01 *N* solutions of sodium hydroxide. The sodium hydroxide was standardized against the hydrochloric acid solutions, using phenolphthalein as the indicator. The sodium hydroxide used contained traces of carbonate, but this was an advantage, as the presence of the carbonate prevents any appreciable excess of either hydrogen ion or of the negative ion of the isonitro compound, which might be produced by a failure to measure out or mix exactly equivalent amounts of the acid and alkali.

Measurement of the Conductivities.—The usual conductivity set was used. It consisted of an Edison potassium hydroxide battery giving 6.7 v., 1000-cycle Leeds and Northrup oscillator, a standard four-dial resistance box with a maximum resistance of 9999 ohms, a Kohlrausch slide-wire bridge of Leeds and Northrup make and a set of Murdock headphones.

Preliminary runs were always made, during which the cell was balanced for capacity, so that during the experiments sharp minima could be obtained without delay.

The conductivities were measured with an accuracy of about 0.1%. However, as the conductivities are only partly due to the conductivities of the isonitro acids the actual accuracy of any measurement is much less, more especially near the end of a run.

Temperature Control.—A gallon (3.8-liter) Dewar flask was used as a thermostat. The bath liquid in every case was in equilibrium with a solid phase, and was stirred mechanically throughout the runs, except during the times when the minima of sound in the phones was being observed. The constant-temperature systems used were carbon tetrachloride in equilibrium with solid carbon tetrachloride, water in equilibrium with ice, benzene in equilibrium with solid benzene, and a mixture

² We thank Messrs. M. A. Joslyn and C. Judah, students at this university, for this preparation of our phenylnitromethane.

of methyl alcohol and water, 1 to 10 by volume, in equilibrium with ice. Although this last is a two-component system, it gave a temperature as constant as the other systems, due to the fact that the heat flow through the Dewar flask during the experiment was equivalent to the heat of solution of an amount of ice quite negligible with respect to the water present in the liquid phase. The temperatures were measured from time to time during the runs, and at different parts of the bath. During none of the runs reported in this article was any variation of temperature greater than 0.05° with respect to both time and place observed.

Owing to the great dilution of the reagents, the heat of the reaction is quite small with respect to the heat capacity of the reacting solutions, so that no rise in temperature greater than 0.1° could have taken place through the mixing of the reagents. The heat of mixing methyl alcohol and water was avoided by making up the solutions with the already mixed solvents.

Experimental Results

The results obtained are shown graphically in eight curves. In these curves the common logarithms of the conductivities due to the isonitro acids are plotted against the times which have elapsed after mixing. In each case the conductivity of the final solution is taken as the unit of conductivity. In every case except Curve 8 the final solution was a $0.005\ N$ solution of sodium chloride. In Curve 8 a slight excess of hydrochloric acid was present. The conductivity of the isonitro acid, expressed in terms of the final solution, was obtained by subtracting the final conductivity from the measured conductivity and dividing the result by the final conductivity. Throughout this paper, this quantity is represented by the letter c .

The value of c is proportional to the concentration of the negative ion of the isonitro acid during any run, as the changes of mobility of the ions are negligible during an experiment (the solutions are very dilute) and the total conductivities never change more than 40% . The results of a typical experiment are shown in Table I.

TABLE I

RATE OF FORMATION OF *p*-NITROPHENOL FROM ITS IONS AT -23.6°

Initial concentrations: *p*-isonitrophenol, $0.005\ N$; sodium chloride, $0.005\ N$

Time, min.	Conductivity, mhos $\times 10^{-4}$	c	Time, min.	Conductivity, mhos $\times 10^{-4}$	c
2	2.350	0.2730	11	1.872	0.0141
3.25	2.140	.1593	14	1.857	.0060
6	1.976	.0704	17	1.850	.0022
8	1.914	.0368	22	1.846	.0000
9	1.891	.0243	Infinity	1.846	.0000

Curves 1, 2, 3, 4, 5 and 6 represent experiments in which the initial concentrations were $0.005\ N$ with respect to the isonitro acid and to

sodium chloride. Curves 1 and 2 represent experiments on phenylisonitromethane at 0 and 5.2°, respectively. Curves 3 and 4 represent experiments on isonitromethane at -23.8 and 0°, respectively. Curves

5 and 6 represent experiments on *p*-isonitrophenol at -23.6 and -9.8°, respectively. Curve 7 represents an experiment on phenylisonitromethane at 0° in which the initial concentration of the isonitro acid was 0.002 *N*,

Fig. 2.—Change of conductivity during the formation of phenylnitromethane from its salt at 5.2°. Initial concn., 0.005 *N*.

while that of the sodium chloride was 0.005 *N*. Curve 8 represents an experiment in which about 10% excess of hydrochloric acid was present,

but which otherwise was identical with the experiment represented by Curve 4.

The curves are all twofold in character. They are concave upwards at the start, but become straight lines as the reactions proceed. The curved portions of the graphs must represent reversible formations of isonitro compounds by combinations of ions, and an accompanying change of structure, as the reactions are not instantaneous. These reactions

may be represented by the type equation, $\text{RCH}=\text{N} \begin{smallmatrix} \text{O} \\ \diagup \end{smallmatrix} \text{O}^- + \text{H}^+ \rightarrow \text{RCH}-\text{N}-\text{OH}$. The linear portion of the graphs must represent isomeric changes of the ions, whose reversals are prevented by very rapid

combinations with hydrogen ion to form the true nitro compounds. These

changes may be represented by the type equations, $\text{RCH}=\text{N} \begin{smallmatrix} \text{O} \\ \diagup \end{smallmatrix} \text{O}^- \rightarrow \text{RCHNO}_2$, and $\text{RCHNO}_2 + \text{H}^+ \rightarrow \text{RCH}_2\text{NO}_2$. The reasons why the experiments show these steps in the reactions are discussed in the following section.

Discussion of Results

If the isonitro acids are partially ionized and change irreversibly to the un-ionized nitro compounds, the courses of the reactions may be followed by conductivity measurements, but the rates of decrease of the

conductivities are not proportional to the rates of formation of the unionized compound, because the fraction of any reactant which is ionized increases as its concentration decreases. However, if we assume that the mobilities of the ions are constant during the reaction, that the activities are proportional to the concentrations and that the purely ionic reactions are rapid with respect to the reactions involving changes of structure,³ then we can obtain equations expressing the rate of change of conductivity as a function of the conductivity, in which the nature of the function depends on the mechanism of the reaction. Thus, if the rate-determining

Fig. 4.—Change of conductivity during the formation of *p*-nitrophenol from its salt: 5, initial concn., 0.005*N*, *T*, −23.6°, 6, initial concn., 0.005*N*, *T*, −9.8°.

reaction is a monomolecular change of the ion of the isonitro acid to an ion which immediately combines with a hydrogen ion to form the nitro compound, the equation will be

$$-dc/dt = kc/[2c/(KR) + 1] \quad (1)$$

where *c* is the conductivity due to the isonitro acid, *k* is the rate of reaction constant, *K* is the dissociation constant of the isonitro acid, while *R* is a proportionality constant connecting the conductivity, *c*, with *i*, the concentration of the ion of the isonitro compound, by the equation

³ All of these assumptions are valid when the solution is very dilute and the change of conductivity during the reaction is small, and both of these conditions exist in our measurements.

$c = Ri$. On the other hand, if the master reaction is a monomolecular change of the undissociated isonitro acid to the nitro compound, then the equation connecting the rate of change of conductivity with the conductivity is

$$-dc/dt = k/KR \cdot [(2c/KR) + 1] \quad (2)$$

These equations would give different types of curves if $\log c$ were plotted against time. The curve corresponding to Equation 1 would be concave downwards at high values of c , but would become a straight line as c decreases. On the other hand, the curve which would be obtained from Equation 2 would be a straight line at the beginning, but would become concave upwards, eventually corresponding to the curve of a second-order reaction. Whether the plot of an actual series of measurements would show these peculiarities would depend on the range of values over which c was measured, and on the values of R and K .

The experimental curves (1, 2, 3, 4, 5, 6) belong to neither of these types. They are all concave upwards at the beginning and then become linear, these changes being too abrupt for the curves to represent a combination of Equations 1 and 2. Variations in temperature of sufficient magnitude to produce the effects observed were quite impossible. The only explanation of such curves is that there are two simultaneous reactions or mechanisms of reaction, one of which becomes subordinate to the other as the reaction proceeds. This disappearance of one of the reactions may be either due to its higher order, or because it reaches a steady state, and since, in every case, the two reactions differ markedly in rate, the steady states must be approximately equal to the true equilibria.

These two alternatives are very easily distinguished, for if equilibrium is reached only after a lapse of time, the slope of the curve depends not only on the conductivity, but also on the time, as long as this time is short. On the other hand if the disturbing reaction becomes insignificant because it is a high-order reaction, then the slope of the curve depends only on the conductivity.

To settle this point Expt. 7 was performed. In this experiment all of the conditions were identical with those of Expt. 1, except the initial concentrations of phenylisonitromethane. A comparison of the curves obtained from the two experiments (Fig. 1) shows that they are not superimposable at the beginning, but that after sufficient time has elapsed to allow the steady state to be established, the two curves become identical. This experiment shows conclusively that there is an equilibrium reaction as well as the irreversible change in the case of the phenylisonitromethane, and since all of the curves belong to the same type, presumably also in the cases of the other substances.

In each case, as the change of conductivity due to the reversible reaction

becomes negligible, the rate of change of the conductivity becomes proportional to the conductivity, and this proportionality continues over the rest of the range of conductivities measured. This is shown by the linear portions of the curves.

If this phenomenon were due to a monomolecular change of an un-ionized substance to the true nitro compound or, to what is equivalent to this, a second-order reaction of the ions to the nitro compound, then a bend in the curve of $\log c$ against time (see Equation 2) should have been noticeable, unless the value of R is very much greater than the corresponding values for organic acids in aqueous solution; for, if in any case the acid were so weak that, throughout the range of concentrations measured, the amount of the substance ionized is negligible, then the conductivities would have fallen over a lower range than those measured. The values of R were measured for phenylisonitromethane and isonitromethane at 0° in the 50% methyl alcohol, and were found to be lower than those of acetic acid in aqueous solution at 0° .

$R = (c_{\text{sodium salt}} + c_{\text{HCl}} - c_{\text{NaCl}})/N$, where $c_{\text{sodium salt}}$, c_{HCl} and c_{NaCl} are the conductivities of the sodium salt of the nitro compound, of hydrochloric acid and of sodium chloride, respectively, all measured at the same very low concentrations. As all of these substances are strong electrolytes, 0.005 N is a low enough concentration for 10% accuracy. In the units in which the conductivities have been expressed in this paper, $c_{\text{HCl}} = 2.84$, $c_{\text{NaCl}} = 1$, c for the sodium salt of phenylnitromethane = 0.69 and c for the sodium salt of nitromethane = 0.90.⁴ Hence, $R = 506$ and 548 for phenylisonitromethane and isonitromethane, respectively.

With such values of R , the variations from apparently monomolecular curves, predicted by Equation 2, would have been noticed for acids which would give $\log c = -1.2$ when the concentration = 0.005 N . Since such a value of $\log c$ is less than those which would be obtained by extrapolating the linear portions of the curves to zero time, the first-order character of the curves cannot be attributed solely to monomolecular reactions of un-ionized molecules, nor to second-order reactions of ions.

On the other hand, if the linear portions of the curves are due to first-order reactions of the ions, the downward concavities of the curves demanded by Equation 1 could be obliterated by the upward concavities due to the reversible reactions, more especially, if the amounts of the true nitro compounds formed before the equilibrium reactions have become negligible are large. This would be the case if the nitro compounds are formed directly from the ions of the isonitro salt and not from those of the substances produced in the reversible reactions, for in that case the

⁴ No correction has been made in these measurements for the hydrolysis of the salt, so that these figures are somewhat too high.

concentrations of the reacting ions at the beginning of the reactions are much higher than those corresponding to the steady state.⁵

Further, if there are any accompanying reactions of the un-ionized molecules, there would be a further obliteration of the downward concavities of the curves expected from Equation 1; but whatever the cause for the great range over which the curves are straight lines, the slopes of the lines at the lower concentrations must represent the rates of reactions which are first order with respect to the ions.

That the linear portion of the curve is to be attributed to a reaction monomolecular with respect to the negative ion was further verified in the case of nitromethane by Expt. 8. In this experiment excess of acid was used, which by its mass-action effect should reduce the rate of the reaction due to the negative ion. That this is the case is strikingly shown by a comparison of Curves 4 and 8.

The mechanism for these isomerization reactions shown by the rate measurements can be represented by the following equations, in which phenylnitromethane has been chosen as the substance depicted.

Equation A represents the reversible reaction which produces the first rapid change of conductivity, and which soon reaches a steady state. Equation B is the rate determining step of the changes which produce phenylnitromethane, and the reaction whose rate is measured by the slope of the linear portion of the curve, while Equation C is a rapid follow reaction, whose rate even in the most dilute solutions measured, must be great in comparison with that of the reverse of Reaction B.

It must be noted that rate measurements do not give direct evidence

⁵ This conclusion is supported by the fact that the extrapolations of the linear portions of the curve to zero time apparently do not give the true value of the ion concentrations corresponding to the steady state at initial total concentrations, for in the case of phenylnitromethane at 0° these values are not proportional to the square root of the initial concentrations, but seem to depend upon how quickly the steady state is reached; while in the case of the other two substances these extrapolations lead to higher values at lower temperatures, and the differences are greater than those which might be expected from changes in the value of *R* due to changes of temperature. This would mean that either the steady states are reached when the total concentrations of isonitro compounds are markedly less than the initial concentrations, or that the degree of ionization increases as the temperature decreases; this latter is unlikely, as generally the formation of a weakly ionized substance from ions is an exothermic process.

for the structural formulas of the substances involved, and that the formulas assigned to the substances involved in these equations are chosen only because they do not involve anomalous valences. While the authors

consider that the structures $\text{C}_6\text{H}_5\text{CH}=\text{N}\begin{smallmatrix} \text{O} \\ \diagup \end{smallmatrix}$ and $\text{C}_6\text{H}_5\text{CH}-\text{N}\begin{smallmatrix} \diagup \text{O} \\ \diagdown \text{OH} \end{smallmatrix}$

probably represent the negative ions of the sodium salt of phenylisonitromethane, and the substance formed by the reversible reaction, respectively, and that this latter substance is probably the isomer of phenylnitromethane which is precipitated from the salt with hydrochloric acid, they do not consider that the formula $\text{C}_6\text{H}_5\text{CH}^- - \text{NO}_2$ truly represents the negative ion which combines with hydrogen ion to form the true nitro compound. In the case of nitromethane, the heat of activation is so small (less than 10,000 cal.) that it seems very unlikely that it could represent the energy necessary to shift an electron from an oxygen to a carbon atom.

It may be noted that the formulation suggested for the reaction removes an anomaly which previously existed. Hantzsch, from his measurements, judged that the isonitromethanes were somewhat stronger acids than

acetic acid, but the suggested formula, $\text{RCH}=\text{N}\begin{smallmatrix} \text{O} \\ \diagup \end{smallmatrix}$ would be ex-

pected to represent acids as strong as sulfurous acid, that is 1000-fold stronger than acetic acid because of the pentavalent nitrogen atom, while there is no reason to believe that the other formula suggested for isonitromethanes, namely, $\text{RCH}-\text{N}\begin{smallmatrix} \diagup \text{O} \\ \diagdown \text{OH} \end{smallmatrix}$ which has neither double bonds

nor pentavalent nitrogen, would be as strong as acetic acid. However,

our experiments have shown that the original acid $\text{RCH}=\text{N}\begin{smallmatrix} \text{O} \\ \diagup \end{smallmatrix}$ changes much too rapidly to permit of an estimate of its strength by such measurements as these, while the acidic properties of the substances $\text{RCH}-\text{N}\begin{smallmatrix} \diagup \text{O} \\ \diagdown \text{OH} \end{smallmatrix}$, as shown by the marked conductivities after the steady

state has been reached, are due to its tautomeric equilibrium with the more acidic $\text{RCH}=\text{N}\begin{smallmatrix} \text{O} \\ \diagup \end{smallmatrix}$ and not to its ionization to H^+ and $\text{RCH}-\text{N}\begin{smallmatrix} \diagup \text{O} \\ \diagdown \text{OH} \end{smallmatrix}$

O^- . The over-all strength of the pseudo acids of the type $\text{RCH}-\text{N}\begin{smallmatrix} \diagup \text{O} \\ \diagdown \text{OH} \end{smallmatrix}$

cannot be judged by extrapolation of the linear portions of the curves, as the values so obtained depend on the relative rates of the reactions

of Types A and B, as well as on the acidity of the intermediate compounds of the type $\text{RCH}-\text{N}-\text{OH}$.

In the cases of phenylnitromethane and *p*-nitrophenol, the final products of the reactions are indubitably the nitro compounds, as these substances can be obtained in large yields from their salts under more drastic conditions than those of these experiments. But nitromethane is much more sensitive to hydrolysis, and it was thought necessary to test experimentally whether the reaction which was measured is an irreversible hydrolysis or the formation of a pseudo acid from its salts, although Hantzsch has assumed it to be of the latter type. The following experiment with its result shows that Hantzsch's assumption is justified.

A 0.01 *N* solution of the sodium salt of isonitromethane was mixed with an equal volume of 0.01 *N* hydrochloric acid at 0°, and allowed to stand for 20 minutes. An equivalent of 0.01 *N* sodium hydroxide solution was then added, and again the solution was allowed to stand for 20 minutes. It was again mixed with an equivalent of 0.01 *N* hydrochloric acid and the conductivity was measured from time to time. The same solvent and the same precautions were used in this experiment as in the other measurements. The conductivity was found to decrease in the same way as in Expt. 4. The value of ϵ , 2.67 minutes after mixing, was 0.03, which is comparable with $\epsilon = 0.01$ after three minutes in Expt. 4, as the solution is only half as concentrated with respect to the isonitro acid in this experiment, owing to the double neutralization.

However, the final solutions obtained in the experiments on nitromethane gradually increase in conductivity on standing at 0°, but this change is slow compared to the changes of conductivity reported in this paper, and cannot produce significant errors.

The Velocity Constants and Heats of Activation

The velocity constants of the reactions are measured by the slopes of the linear portions of the curves, multiplied by 2.3 and divided by 60 to bring the units to reciprocal seconds. The values are given in Col. 3 of Table II. In each case they are the average values obtained from several independently drawn curves. They are velocity constants for the Type B reactions.

The heats of activation per mole of these same reactions are obtained from the rate constant measured at different temperatures by the usual equation, $Q = -R\Delta \ln k/\Delta(1/T)$, where k is the velocity constant and Q the heat of activation. The heats of activation in calories per mole are given in Col. 4 of Table II.

In Table II the values of B , another constant characteristic of reactions, are given in the last column. The logarithm of a monomolecular-reaction

constant may be expressed by the equation $\log_{10} k = B - Q/(2.3 \times RT)$. The reaction is thus determined by the constants B and Q .

TABLE II
VELOCITY CONSTANTS AND HEATS OF ACTIVATION

Substance	Temp., °C.	Velocity constant, sec. ⁻¹	Heat of activation per mole	B
Phenylnitromethane	5.2	1.78×10^{-4}	22000 ± 2000	13.56
Phenylnitromethane	0	8.34×10^{-5}		
Nitromethane	0	7.45×10^{-3}	8450 ± 600	4.66
Nitromethane	-23.8	1.68×10^{-3}		
<i>p</i> -Nitrophenol	-9.8	8.44×10^{-3}	4250 ± 800	1.47
<i>p</i> -Nitrophenol	-23.6	5.37×10^{-3}		

Inspection of Table II shows that Q and B vary widely for the different reactions. Q and B are both greatest for the slowest reacting substance, phenylnitromethane, and smallest for the fastest reacting substance, *p*-nitrophenol, and that B is large when Q is large. The differences in the Q 's and B 's for the various substances are more significant than a comparison of the rates, for the values of Q and B are such that if the reactions were carried out above 50°, the phenylnitromethane would be the fastest reacting of the three substances, and *p*-nitrophenol the slowest.

Addenda

In the body of the paper the equations

$$-d_i/dt = k_i \left(\frac{2c}{KR} + 1 \right) \quad (1) \quad -dc/dt = k_i' KR c^2 \left(\frac{2c}{KR} + 1 \right) \quad (2)$$

are given without derivation. The mathematical derivations are quite simple. The fundamental assumptions that the mobilities of the ions are constant and that the mass law is valid for the electrolytic dissociation may be expressed by

$$c = Ri \quad (3)$$

and

$$i^2/u = K \quad (4)$$

respectively, where i is the concentration of the ionized reactant, u that of the undissociated reactant, R is the proportionality constant between the concentrations of the ions and the conductivity of the solution due to the isonitro acid and K is the dissociation constant of the acid.

Since one mole of reactant forms one mole of resultant, the rate of formation of the resultant is equal to the rate at which the total reactant is used up, that is,

$$dx/dt = -d(i + u)/dt \quad (5)$$

where x is the concentration of the resultant.

Combining Equations 4 and 5 and eliminating u ,

$$dx/dt = -di/dt [(2i/K) + 1] \quad (6)$$

Now dx/dt depends upon the mechanism of the reaction, and for monomolecular reactions of the negative ion or of the undissociated acid,

$$dx/dt = ki \quad (7)$$

or

$$dx/dt = ku \quad (8)$$

Hence,

$$-di/dt = ki \left(\frac{2i}{K} + 1 \right) \quad \text{or} \quad -di/dt = k/K \cdot i^2 \left(\frac{2i}{K} + 1 \right)$$

Substituting c for i in these equations gives

$$-dc/dt = kc \left(\frac{2c}{KR} + 1 \right) \quad \text{and} \quad -dc/dt = k/KR \cdot c^2 \left(\frac{2c}{KR} + 1 \right)$$

When c is small, these equations become equivalent to the usual equations for monomolecular and dimolecular reactions, respectively.

In Expt. 8 excess of acid is present. If the concentration of the excess acid is called a , then Equation 4 becomes $i(i+a)/u = K$, while the other fundamental equations remain unchanged. Consequently $dx/dt = -(di/dt)[(2i/K) + (a/K) + 1]$ instead of $dx/dt = -(di/dt)[(2i/K) + 1]$. When i becomes very small compared to a , then $dx/dt = -di/dt[(a/K) + 1]$, so that if the reaction is monomolecular with respect to the ions, then

$$-di/dt = \left[k \left(\frac{a}{K} + 1 \right) \right] i, \quad \text{or} \quad -dc/dt = \left[k \left(\frac{a}{K} + 1 \right) \right] c.$$

The reaction is thus still first order, but the constant is reduced from k to $k/[(a/K) + 1]$.

Summary

The isomerization of isonitromethane, phenylisonitromethane and *p*-isonitrophenol to the corresponding nitrocompounds has been investigated by measurements of the rates of the changes of electrical conductivity which occur when solutions of the sodium salts of these substances are mixed with hydrochloric acid.

In all these cases the rates of decrease of the conductivity were found to diminish very rapidly at first, and after some time were observed to become proportional to the conductivities, due to the isonitro compounds, and to remain so to as low values as it was possible to measure.

The twofold character of the curves corresponding to these results has been explained by assuming another type of isonitro compound which is formed by reversible reactions as, for instance, such a reaction as

The persistent proportionality between the rates of change of the conductivities and the conductivities of the isonitro acids has been taken as a strong indication that formations of the true nitro compounds occur through comparatively slow changes of the ions of the isonitro acids to

ions which combine rapidly with hydrogen ion to form the nitro compounds.

The velocity constants of these second reactions have been measured at two temperatures for each of the substances. The heats of activation of these reactions have been calculated from the results.

The heats of activation have been found to differ very markedly for the three substances, that for phenylisonitromethane being more than 10,000 cal. greater than that for nitromethane.

The heat of activation in the case of *p*-isonitrophenol has been found to be very small, being less than 5000 cal.

RESEARCHES ON THIAZOLES. II. THE NITRATION AND REDUCTION OF 2-MERCAPTOBENZOTHIAZOLE AND ITS SUBSTITUTED DERIVATIVES

BY JAN TEPPEMA AND L. B. SEBRELL

RECEIVED FEBRUARY 21, 1927

PUBLISHED JULY 5 1927

In a previous paper¹ a new method of preparation for 2-mercaptobenzothiazole was given. This method was extended to the preparation of several new 2-mercaptobenzothiazoles which had hitherto not been described.

It is the purpose of the present paper to outline the results obtained by nitration and subsequent reduction of 2-mercaptobenzothiazole and its derivatives as given in the first paper.

Bogert² has shown that the nitration of 2-phenylbenzothiazole gives 6-phenyl-2-mercaptobenzothiazole. We were unable to fix the position of the nitro group in nitro-2-mercaptobenzothiazole by use of the procedure followed by Bogert. However, we were able to prove by another way that the nitro group is in Position 6.

The work of Kwaysser³ and Mylius⁴ has made available 2-amino-5-nitrothiophenol. After reduction this compound, treated with sodium hydrosulfide and carbon disulfide according to our previously described method gave 6-amino-2-mercaptobenzothiazole; m. p., 263°. The reduction product of nitrated 2-mercaptobenzothiazole after purification melted at 260°. A mixed-melting-point determination gave no decrease in melting point. We, therefore, conclude that on nitration the nitro group enters the ring in 2-mercaptobenzothiazole in Position 6.

These reactions are

¹ Teppema and Sebrell, *THIS JOURNAL*, **49**, 1748 (1927)

² Bogert, *ibid.*, **44**, 826 (1922)

³ Kwaysser, *Ann.*, **277**, 240 (1893)

⁴ Mylius, *Dissertation*, University of Berlin, 1883.

Another amido-2-mercaptobenzothiazole, m. p. 216°, was described by us in our previous paper. From its method of preparation it must be 5-amino-2-mercaptobenzothiazole.

Attempts to prepare 5-nitro-2-aminothiophenol by fusion of the nitration product of 2-mercaptobenzothiazole were unsuccessful. Heating under pressure with aqueous ammonia gave 6-nitro-2-aminobenzothiazole.

By diazotization and Sandmeyer reaction of 6-amino-2-mercaptobenzothiazole the corresponding 6-chloro-2-mercaptobenzothiazole is formed. Benzaldehyde condenses readily with the amino group to give 6-benzal-amino-2-mercaptobenzothiazole.

A similar series of derivatives is formed by nitrating the 5-chloro-2-mercaptobenzothiazole. In this compound the position of the nitro group has not been definitely proved but it is believed to be in Position 6.

From 1,2,4-toluylenediamine and sulfur the corresponding disulfide was prepared according to Schultz and Beyschlag.⁵ By reaction with sodium hydrosulfide and carbon disulfide the 5-amino-6-methyl-2-mercaptobenzothiazole is produced. It gives all the reactions characteristic of an aminomercaptobenzothiazole.

In this paper the melting points given are uncorrected.

Experimental Part

6-Nitro-2-mercaptobenzothiazole.—Fifty g. of 2-mercaptobenzothiazole was dissolved in 250 g. of sulfuric acid, and a mixture of 40 g. of fuming nitric acid and 55 g. of concd. sulfuric acid was slowly dropped in while cooling the reaction mixture with ice and salt. The solution was stirred during the addition of the acid mixture. After all the nitric acid solution is added, the solution is stirred in the cold for one hour more. The solution is then poured onto ice, the precipitate filtered, washed with water and dried; yield, 63 g.; calcd., 65 g. By boiling this compound with aqueous ammonia and repeating this with the residue most of this nitration product could be brought in solution.

From the red solution thus obtained, a yellow precipitate was formed by the addition of dilute acid. After filtering and drying, this material was crystallized from glacial acetic acid, giving yellow needles; m. p., 255–257°.

Anal. Calcd. for $\text{C}_7\text{H}_4\text{O}_2\text{N}_2\text{S}_2$: S, 30.19; N, 13.20. Found: S, 29.94; N, 13.48.

The crude nitration product which is obtained by pouring the nitric acid solution into ice water is a mixture of nitro-2-mercaptobenzothiazole and its disulfide. Aqueous ammonia dissolves in the cold only the free mercaptan. When the residue was heated with aqueous ammonia it also dissolved and gave the same nitro compound on addition of acid.

This is a remarkable case of the influence of the nitro group on the stability of the sulfur-to-sulfur bond. Whereas the disulfide of 2-mercapto-

⁵ Schultz and Beyschlag, *Ber.*, **42**, 743 (1909).

benzothiazole does not give the free mercaptan easily by boiling with alkalis, introduction of the nitro group loosens the bond between the sulfur atoms.

Amido-2-mercaptobenzothiazole.—The reduction of nitro-2-mercaptobenzothiazole can easily be accomplished by sodium hydrosulfide.

Fifty g. of the nitro compound was suspended in a solution of 75 g. of sodium sulfide, $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$, in 250 cc. of water which had previously been saturated with hydrogen sulfide. The mixture was then heated on a sand-bath under reflux for 24 hours while hydrogen sulfide was bubbled through the solution.

The solution was acidified with dil. acetic acid and heated on a steam-bath to complete the coagulation of the precipitate. The mixture of the amido compound and sulfur was filtered and the solid extracted with hot aqueous ammonia. Addition of dil. acetic acid yielded amido-2-mercaptobenzothiazole as a yellow-white precipitate which could be crystallized from aniline. It may also be purified by dissolving it in pyridine and reprecipitating with chloroform; m. p., 260° .

Anal. Calcd. for $\text{C}_7\text{H}_6\text{N}_2\text{S}_2$: S, 35.2; N, 15.35. Found: S, 34.82; N, 15.50.

This amino-2-mercaptobenzothiazole was diazotized as described below and coupled with β -naphthol. It gave a beautiful red dye.

The complete possibilities of utilizing the various amino-2-mercaptobenzothiazoles as intermediates in the synthesis of dyes have not been entirely developed. Further work is being done and will be reported in a separate communication.

A considerable improvement in the preparation of 6-amido-2-mercaptobenzothiazole could be made by omitting the isolation of the free nitro-2-mercaptobenzothiazole.

The crude nitration product of 2-mercaptobenzothiazole was reduced with sodium hydrosulfide and gave the corresponding amido-2-mercaptobenzothiazole in almost quantitative yield. It was purified as described above.

Position of Nitro Group.—The following experiments were carried out to prove the constitution of nitro-2-mercaptobenzothiazole, of which only the last method was successful.

(1) As already mentioned above, diazotized *p*-nitro-aniline did not react with amido-2-mercaptobenzothiazole according to the method described by Bogert² for amino-2-phenylbenzothiazole.

(2) The second method is the fusion of nitro-2-mercaptobenzothiazole with potassium hydroxide to give a nitro-aminothiophenol. However, through the formation of hydrogen sulfide during the fusion this compound seems to be reduced, and no definite compound could be isolated from the fusion.

(3) To avoid the strong action of potassium hydroxide, the nitromercaptobenzothiazole was heated with concd. aqueous ammonia under pressure.

Three g. was heated with 40 cc. of aqueous ammonia (d, 0.95) for four hours at 160° . A red solution with crystals was obtained. The solution was filtered, diluted with twice

the amount of water and neutralized. The precipitate formed was unchanged nitro compound.

The residue on the filter was crystallized from alcohol and treated with bone black; yellow needles were obtained; melting point, 249°. It proved to be different from nitro-2-mercapto-benzothiazole, as mixed with this compound the melting point was 218°.

This compound is soluble in acid and insoluble in alkali. The yield under these conditions was small and most of the final product was unchanged nitro compound. The analysis for sulfur and nitrogen showed it to be 2-amido-6-nitrobenzothiazole, and its formation can be formulated as follows.

Anal. Calcd. for $\text{C}_7\text{H}_3\text{O}_2\text{N}_2\text{S}$: S, 16.41; N, 21.5. Found. S, 16.48; N, 20.75.

(4) A fourth method consists in the preparation of 5-nitro-2-oxybenzothiazole and treating this compound with aqueous ammonia according to Kwaysser³ to give 5-nitro-2-aminothiophenol. This compound is quite unstable when not dry, as it is easily oxidized to the corresponding disulfide.

It has been shown in a previous paper¹ that 2-mercaptobenzothiazole could be obtained from *o*-amidothiophenol with carbon disulfide in two ways. The new method described consisted in passing hydrogen sulfide, previously saturated with carbon disulfide, through an alkaline solution of the thiophenol.

This same procedure was applied to the reduction product of 5-nitro-2-amidothiophenol.

Reduction of 5-Nitro-2-amidothiophenol.—Four g. of 5-nitro-2-amidothiophenol was heated with 10 g. of granulated tin in 60 cc. of hydrochloric acid (1:1). The solution was boiled under reflux for three hours. The clear solution then obtained was diluted with much warm water and the tin precipitated with hydrogen sulfide. The filtrate from the tin sulfide was concentrated and neutralized with sodium hydroxide. Twenty g. of $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$ was then added and hydrogen sulfide, previously saturated with carbon disulfide, was passed through the solution, which was kept at 80° for ten hours.

On acidification with dil. acetic acid a colorless precipitate was formed. This was filtered, redissolved in aqueous ammonia and reprecipitated with dil. acetic acid; yield, 3 g.

The dried material was crystallized from aniline; m. p., 263°. It was 6-amino-2-mercaptobenzothiazole.

Mixed with the reduction product of nitro-2-mercaptobenzothiazole, no decrease in melting point was observed.

The conclusion is, therefore, that the nitration of 2-mercaptobenzothiazole under the conditions mentioned yields 6-nitro-2-mercaptobenzothiazole.

2-Mercapto-6-benzalamidobenzothiazole.—Nine and one-tenth g. of 2-mercapto-6-amidobenzothiazole was suspended in 100 cc. of alcohol and 7.5 cc. of freshly-distilled benzaldehyde was added. After heating for one and one-half hours the reaction mixture consisted of yellow needles. By addition of more alcohol these crystals dissolved in the hot solution and, on cooling, light yellow crystals separated; m. p., 226°.

Anal. Calcd. for $\text{C}_{10}\text{H}_{11}\text{N}_3\text{S}_2$: N, 10.37. Found: 10.13.

6-Chloromercaptobenzothiazole.—This compound was obtained from 6-amido-2-mercaptobenzothiazole by the well-known Sandmeyer reaction. As 6-amido-2-mercaptobenzothiazole is almost insoluble in water and does not form salts with acids, a modification of the usual way of diazotation was made. The following proved to be successful: 5 g. of 6-amido-2-mercaptobenzothiazole was dissolved in dil. sodium hydroxide (1:10) and this solution mixed with a solution of 3.8 g. of sodium nitrite in a little water.

The reason why twice the calculated amount of sodium nitrite is used is that part of the nitrous acid, set free, will oxidize the free mercaptan to its disulfide. In case the calculated amount of sodium nitrite is used, the diazotation will, therefore, be incomplete.

The solution was dropped slowly into 100 cc. of concd. hydrochloric acid, with ice cooling. If the solution was added carefully, the final solution did not contain any undissolved matter, but was slightly turbid. This solution was poured slowly into a dilute hydrochloric acid (1:1) solution of 12 g. of cuprous chloride, which was kept at 60–70°. A yellow-brown precipitate was formed. The reaction mixture was diluted with an equal volume of water and filtered, and the residue washed with water. The product obtained, being 6-chloro-2-mercaptobenzothiazole disulfide, was not isolated, but reduced with sodium hydrosulfide to the free mercaptan.

The solid, still wet, was mixed with 20 g. of $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$ and 250 cc. of water, and hydrogen sulfide was passed through for four hours with heating. The final solution was filtered from a little dark colored solid and the filtrate acidified with dil. acetic acid. The precipitate was filtered and washed. It was freed from sulfur by dissolving in dilute aqueous ammonia and reprecipitating with dil. acetic acid. After being dried it was crystallized from aniline; m. p. (unsharp), 245°.

Anal. Calcd for $\text{C}_7\text{H}_4\text{NS}_2\text{Cl}$ Cl, 17.61. Found. 17.79.

Attempts to Obtain 6-Chloro-2-mercaptobenzothiazole by Chlorination of 2-Mercaptobenzothiazole.—When chlorine was passed through a solution of 2-mercaptobenzothiazole in carbon tetrachloride or *sym.*-tetrachloro-ethane, either at room temperature or at the boiling points of these solvents, no chlorinated 2-mercaptobenzothiazole was obtained.

In the first solvent only the disulfide of the mercaptan was formed. Chlorination in tetrachloro-ethane at the boiling point of this solvent gave an oil, b. p. 235–248°, with the characteristic odor of chlorophenyl mustard oil.

It was found, however, that 6-chloro-2-mercaptobenzothiazole is formed in a very small yield when 2-mercaptobenzothiazole reacts with chlorine in the presence of a small amount of iron.

Instead of 2-mercaptobenzothiazole, 2-mercaptobenzothiazole disulfide was used, as the latter product is produced as an intermediate compound. Ten g. of 2-mercaptobenzothiazole disulfide was dissolved in chloroform and 0.5 g. of iron powder added to the solution. Chlorine was passed through the boiling solution for five hours. After evaporation of the solvent at room temperature, the residue was extracted with chloroform to remove unchanged disulfide. The insoluble residue showed halogen present by qualitative test. The amount was small in comparison with unchanged disulfide.

One-half g. of this material was reduced with sodium hydrosulfide. A clear solution was obtained which, on acidification with dil. acetic acid, gave a white precipitate.

This compound was filtered, washed and redissolved in dil. aqueous ammonia. Dil. acetic acid precipitated a white material which, after filtering and drying, was crystallized from aniline, giving colorless needles; m. p., 230-235°. The amount of this compound was too small to be purified further.

To prove that it was identical with 6-chloro-2-mercaptobenzothiazole it was mixed with 6-chloro-2-mercaptobenzothiazole, m. p., 245°, previously obtained from 6-amino-2-mercaptobenzothiazole. The melting point was 235-240°, showing that it was identical with 6-chloro-2-mercaptobenzothiazole.

Nitro-5-chloro-2-mercaptobenzothiazole.—The same procedure as described for the nitration of 2-mercaptobenzothiazole was followed for 5-chloro-2-mercaptobenzothiazole.

Fifty g. of 5-chloro-2-mercaptobenzothiazole was dissolved in 175 cc. of concd. sulfuric acid and a mixture of 50 g. of fuming nitric acid and 70 g. of concd. sulfuric acid was dropped in gradually, cooling with ice and salt, while the solution was stirred mechanically.

After all of the mixed acid was added, stirring was continued for one hour and the mixture then poured into ice water. The yellow precipitate was filtered and digested with hot, aqueous ammonia. After repeating this thrice most of the nitro compound was dissolved and could be precipitated with acids, yield (dry), 50 g. It crystallized from acetic acid in yellow flakes; m. p., 190-192°.

Anal. Calcd. for $C_7H_4ClN_2O_2S_2$. N, 11.3, Cl, 14.4. Found. Cl, 14.30; N, 11.21.

Amido-5-chloro-2-mercaptobenzothiazole.—To prepare amido-5-chloro-2-mercaptobenzothiazole from nitro-5-chloro-2-mercaptobenzothiazole, sodium hydrosulfide could not be used as a reducing agent as it will not only reduce the nitro group but also substitute the chlorine atom to a certain extent.

Tin and hydrochloric acid were used as reducing agents. Fifty-five g. of nitro-5-chloro-2-mercaptobenzothiazole was added to a mixture of 100 g. of tin and 300 cc. of concd. hydrochloric acid. The solution was refluxed for four hours, whereby the yellow color of the suspended nitro-5-chloro-2-mercaptobenzothiazole disappeared. After dilution with water the solution was filtered and the residue digested with hot, aqueous ammonia.

The filtrate, acidified with dil. acetic acid, gave a white precipitate which crystallized from aniline, giving colorless needles; m. p., 240°.

Anal. Calcd. for $C_7H_6N_2S_2Cl$. S, 29.56; N, 12.93. Found: S, 29.17; N, 11.94.

Benzalamido-5-chloro-2-mercaptobenzothiazole. Two g. of amido-5-chloro-2-mercaptobenzothiazole was boiled with 50 cc. of alcohol and 2 cc. of benzaldehyde for one hour. The solution was treated with bone black and filtered hot. Yellow needles were obtained; m. p., 242°.

Anal. Calcd. for $C_{14}H_8N_2S_2Cl$. S, 21.01. Found: 21.02.

5-Amido-6-methyl-2-mercaptobenzothiazole.—This compound can easily be prepared from *m*-toluylenediamine disulfide.⁵

Thirty-five and one-half g. of *m*-toluylenediamine was dissolved in 284 cc. of alcohol and 18.5 g. of sulfur was added. The solution was heated under reflux on a water-bath for four hours. After distilling off the alcohol the residue was treated with a solution of

100 g. $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$ in 200 cc. of water which had been previously saturated with hydrogen sulfide and carbon disulfide. The mixture was heated on a sand-bath while hydrogen sulfide (saturated with carbon disulfide vapor) was bubbled through for five hours. The red solution was acidified with dil. acetic acid. First a sticky, yellow precipitate was formed, from which the remaining solution was decanted. On further acidification a white, flocculent precipitate was formed, which was filtered off and washed with water. The crude material was treated with aqueous ammonia, leaving the sulfur behind. The ammoniacal solution was acidified (cold) with dil. acetic acid. The precipitate formed was filtered, dried and crystallized from freshly distilled aniline; yield, 15.5 g.; m. p., 205–213°. It was further purified by crystallizing it twice from alcohol, raising the melting point to 220°.

Anal. Calcd. for $\text{C}_8\text{H}_8\text{N}_2\text{S}_2$: S, 32.65. Found: 32.84.

This 5-amido-6-methyl-2-mercaptobenzothiazole is a starting material for a new series of derivatives which contain a methyl group in Position 6 and any other substituent in Position 5.

5-Chloro-6-methyl-2-mercaptobenzothiazole.—Ten g. of 5-amido-6-methyl-2-mercaptobenzothiazole was dissolved in dil. sodium hydroxide solution and this was mixed with a solution of 7 g. of sodium nitrite in a little water. This solution is then dropped slowly into 200 cc. of concd. hydrochloric acid, with cooling. After standing for half an hour in ice water the diazotized solution was added slowly to a solution of 24 g. of cuprous chloride in hydrochloric acid solution ($1\text{HCl} \cdot 1\text{H}_2\text{O}$) which was kept at 60–70°. After all had been added the solution was diluted with an equal amount of water. The precipitate was filtered off, washed and dried. It was crystallized from dil. alcohol; m. p. (unsharp), 221–223°. The analysis indicates an impure product.

Anal. Calcd. for $\text{C}_8\text{H}_8\text{NS}_2\text{Cl}$: S, 29.70; N, 6.49. Found: S, 30.64; N, 5.72.

Benzal-5-amido-6-methyl-2-mercaptobenzothiazole. Five and nine-tenths g. of 5-amido-6-methyl-2-mercaptobenzothiazole was dissolved in 100 cc. of alcohol, and 3.18 g. of benzaldehyde was added to the warm solution. After 2 minutes' heating the solution solidified. Much alcohol was added, but apparently the benzal compound is very difficultly soluble in alcohol. The suspension was refluxed for ten minutes more and then cooled and filtered; yield, 7.5 g. of colorless crystals, m. p., 253°.

Anal. Calcd. for $\text{C}_{13}\text{H}_{12}\text{N}_2\text{S}_2$: S, 22.53; N, 9.86. Found: S, 22.48; N, 9.67.

Summary

1. The nitration products of 2-mercaptobenzothiazole and 5-chloro-2-mercaptobenzothiazole have been prepared and studied.
2. The position of the nitro group in nitro-2-mercaptobenzothiazole has been proved to be in the benzene ring in Position 6.
3. The reduction products of the above nitromercaptobenzothiazoles have been prepared, and from the amino compounds thus formed the aldehyde derivatives were prepared. By the Sandmeyer reaction the amino group was replaced by halogen.
4. From *m*-toluylenediamine disulfide a 5-amido-6-methyl-2-mercaptobenzothiazole was prepared. This gave also the corresponding aldehyde derivative, and by the Sandmeyer reaction the 5-chloro-6-methyl-2-mercaptobenzothiazole was obtained.

THE ELECTRON-SHARING ABILITY OF ORGANIC RADICALS

BY R. M. HIXON AND I. B. JOHNS

RECEIVED MARCH 5, 1927

PUBLISHED JULY 5, 1927

Ostwald¹ pointed out that certain elements or radicals, when substituted in organic acids, affected the dissociation constant in a uniform manner. Those elements, or radicals, which when substituted into acetic acid caused an increase in the dissociation constant, he called negative, and those which caused a decrease, positive. Wegscheider² summarizes the available data and puts them into a tabulated form from which it is possible to calculate the dissociation constant of various substituted acids. Many limitations to these generalizations, such as those of Bader³ and Hantzsch⁴ have been pointed out.

In 1901, Noyes and Lyon⁵ pointed out that if all reactions involving the decomposition of molecules are preceded by an ionization of the parts of the molecules, it would follow that elementary molecules as well must ionize into positive and negative parts. A few years later, Abegg⁶ stated that all elements are amphoteric, that is, exhibit both positive and negative electricity. We may interpret the generalizations of these pioneers to mean that the electron-sharing ability of any atom depends upon the strength of the other groups to which it is linked.

This generalization is involved in all of the recent theories⁷ which attempt to explain the distribution of affinity in the carbon compounds. All of these theories are qualitative in nature and the success of the manipulation depends upon reading into them a degree of stress or strain which can only be acquired by experience. The introductory statement used by Fry⁸ to one of his papers is especially significant. "The present series of papers is a further extension of the electronic principles of valence in an endeavor to interpret only a few of the many stereochemical problems now confronting us and concerning which Cohen tersely remarks: 'It must be confessed that we are still profoundly ignorant of the change which substituents effect in the character of the molecule as a whole, the causes which determine the rules of orientation-- and a host of other phenomena of a similar nature.' "

⁵ Noyes and Lyon, *THIS JOURNAL*, **23**, 460 (1901).

⁶ Abegg, *Z. anorg. Chem.*, **39**, 330 (1904).

⁷ A general summary of these theories is given by Henrich, Johnson and Hahn in "Theories of Organic Chemistry," John Wiley and Sons, New York, 1922, pp. 75-168.

⁸ Fry, *THIS JOURNAL*, **36**, 248 (1914).

The confusion is due mostly to the lack of a quantitative measure of the "electron-sharing ability" of the various carbon radicals. Derick⁹ attempted to establish such a standard by means of the acidic and basic dissociation constants of the various hydroxides. We may use the following electronic explanation for Derick's reasoning. (a) In water, hydrogen and oxygen are balanced. There is an equal tendency for the formation of hydrogen and hydroxyl ions. (b) If one hydrogen is replaced by an element or radical R with a greater tendency than hydrogen to take on an electron, the compound tends to ionize into $\text{RO}^- + \text{H}^+$. Furthermore, the degree of the ionization would be a measure of the "negativity" of R. (c) If one hydrogen is replaced by an element or radical R with a greater tendency than hydrogen to give up an electron, the compound tends to ionize into $\text{R}^+ + \text{OH}^-$. Furthermore, the degree of this ionization would be a measure of the "positivity" of R. He then uses the following mathematical value for these terms. Positivity = $-1000/\log K_{\text{basic}}$; negativity = $-1000/\log K_{\text{acidic}}$. Ostwald had previously considered this standard but had rejected it in favor of the standard mentioned above, based on acetic acid, because the "non-ionization" of such a large group of compounds makes this standard impossible to apply experimentally. For this very reason, Derick's treatment of the subject is limited to the organic acids.

An Activity Series of Organic Radicals.—This difficulty which limits the applicability of Derick's work can easily be avoided by the following reasoning. If the electron theory of valence holds, then the polar properties of any series of compounds such as $\text{R}(\text{OH})$, $\text{R}(\text{COOH})$, $\text{R}(\text{CH}_2\text{COOH})$, $\text{R}(\text{CH}_2\text{CH}_2\text{COOH})$, RNH_2 , RSH , $\text{RAsO}(\text{OH})_2$, etc., must be a function of the "electron-sharing ability" of R if we exclude from consideration under R all groupings which themselves have polar linkages.

An examination of all of the values given in Landolt-Bornstein for the dissociation constants of the acids and amines makes possible the comparison shown in Table I for the dissociation constants of $\text{R}(\text{NH}_2 \cdot \text{H}_2\text{O})$, $\text{R}(\text{COOH})$, $\text{R}(\text{CH}_2\text{COOH})$, $\text{R}(\text{CH}_2\text{CH}_2\text{COOH})$ and ROH .

Representative values from Table I are plotted in Fig. 1 against an arbitrary abscissa designated as "electron-sharing ability of various radicals." In plotting these results, it was observed that the curves were exponential no matter what units were chosen for the x axis. Accordingly, an arbitrary curve $y = \log K^{10} = -20(e^{0.05x} - 0.75)$ was drawn and the dissociation constants for the various amines $\text{R}(\text{NH}_2 \cdot \text{H}_2\text{O})$ were located on the curve, thereby fixing the position of R along the x axis. The corresponding values for the other derivatives of R were then located and a smooth

⁹ Derick, *THIS JOURNAL*, 33, 1152, 1162, 1181 (1911); 34, 74 (1912).

¹⁰ In Fig. 1 $y = \log K$. This value may be quickly approximated from the exponent given in Table I for the dissociation constant K .

curve was drawn through them. It was found that the following mathematical expressions held for the dissociation constants of the various polar compounds listed.

$$R(NH_2 H_2O), y = \log K_1 = -20(e^{0.05x} - 0.75) \quad (1)$$

$$R(COOH), y = \log K_2 = 20(e^{0.5x-5.6} - 0.24) \quad (2)$$

$$R(CH_2COOH), y = \log K_3 = 20(e^{0.5x-6.6} - 0.24) \quad (3)$$

$$R(CH_2CH_2COOH), y = \log K_4 = 20(e^{0.5x-7.6} - 0.24) \quad (4)$$

Since the slope of the ROH curve is questionable, no equation has been derived.

For any reaction in which we start with the reactants at unit concentration and finish with the resultants at unit concentration, the thermodynamic expression $-\Delta F = RT \ln K$ or $-\Delta F = 2.3 RT \log K$ holds for the relationship between the "free-energy change" and the equilibrium constant. The application of this expression¹¹ to the present data will be as precise as the Ostwald dilution law. It would follow that the free energy of ionization of any polar derivative of the series of radicals

Fig 1.—Relation between the dissociation constants of different polar derivatives of various radicals.

R could be expressed as a function of the electron-sharing ability x ; for example,

$$R(NH_2 H_2O), \quad \Delta F = 46 RT(e^{0.5x} - 0.75) \quad (5)$$

$$R(COOH), \quad -\Delta F = 46 RT(e^{0.5x} - 0.24) \quad (6)$$

$$R(CH_2COOH), \quad \Delta F = 46 RT(e^{0.5x} - 0.24) \quad (7)$$

$$R(CH_2CH_2COOH), \quad \Delta F = 46 RT(e^{0.5x} - 0.24) \quad (8)$$

For each series this may be put into the general form

$$-\Delta F = k RT(e^{ax} - b - c) \quad (9)$$

from which may be derived the expression for x

$$x = \frac{1}{a} \ln \left(e - \frac{\Delta F}{kRT} \right) + \frac{b}{a} \quad (10)$$

The free-energy change represents the work required to separate by means of the hypothetical equilibrium box, one mole of the undissociated acid

¹¹ Acknowledgment is made to Professor Anson Hayes for suggesting this method of treating the "free-energy change."

or base into the normal solutions of the two respective ions. If this is expressed in electrical units, the number of faradays, nF , per mole will be unity in all of the above cases and the potential E only will vary. Equations 9 and 10 could then be written

$$E = \frac{kRT}{nF} (e^{ax-b} - c) \quad (11)$$

$$x = \frac{1}{a} \ln \left(c - \frac{EnF}{kRT} \right) + \frac{b}{a} \quad (12)$$

where E represents the potential of the ions of the normal acid or base and is the only variable in each series, the temperature being kept constant. It will be seen that E is an exponential function of the electron-sharing ability of the substituent group R . The term "electron-sharing ability" receives a mathematical expression but its mechanical significance is not clear. It is also apparent that the free energy of ionization, or the ionic potential of a member of any series can be calculated from the corresponding member of any of the other series; that is, combining Equations 5 and 6

$$\frac{-\Delta F_{\text{acid}}}{\Delta F_{\text{base}}} = \frac{F_{\text{acid}}}{-E_{\text{base}}} = \frac{e^{0.5x-5.6} - 0.24}{e^{0.05x} - 0.75} \quad (13)$$

The Effect of Intervening CH_2 Units upon the Properties of Polar Groups.—Derick has stated a "rule of thirds" for the relationship of the dissociation constants of the acids substituted in α , β , γ , δ positions. This generalization holds very well for the acids substituted by the strongly negative groups but does not hold for the less negative substituents.

TABLE II

OBSERVED AND CALCULATED VALUES FOR $-\log K$ OF SUBSTITUTED ACIDS WHEN VARIOUS SUBSTITUENTS "R" ARE REMOVED UNIFORM DISTANCES FROM THE CARBOXYL GROUP

The distance is measured by the number of intervening CH_2 units

	Intervening CH_2 units = s	R = (Cl)		R = (Br)		R = (I)		R = (CH_2Cl)		R = (CH_2Br)		R = (CH_2I)

^a This value is extrapolated from the curves in Fig. 1.

The more general exponential Equation 9 fits all cases for which data are at present available.

Table II presents the measured and calculated values for $-\log K$ when various substituents "R" are removed uniform distances¹² from the carboxyl group, the distance being measured by the number of intervening CH_2 units.

Designating the number of intervening CH_2 units by z , the formulas used for the calculated values in Table II are as follows.

For	$\log K =$	For	$\log K =$
Cl	$20(e^{-0.8z-1.43} - 0.25)$	CH_2I	$20(e^{-0.8z-2.36} - 0.25)$
Br	$20(e^{-0.8z-1.43} - 0.25)$	$\text{C}_2\text{H}_5\text{OOC}$	$20(e^{-0.8z-1.83} - 0.25)$
I	$20(e^{-0.8z-1.56} - 0.25)$	C_6H_5	$20(e^{-0.5z-3.1} - 0.25)$
CH_2Cl	$20(e^{-0.8z-2.23} - 0.25)$	$\text{CH}_2=\text{CH}$	$20(e^{-0.4z-3.3} - 0.25)$
CH_2Br	$20(e^{-0.8z-2.21} - 0.25)$	CH_3	$20(e^{-z-4.6} - 0.25)$
		H	$20(e^{-1.6-2.6} - 0.25)$

These equations are of the same general form as Equations 1, 2, 3 and 4 and there would be the same general relationships between free energy of ionization and z as that expressed in Equation 10 for x

$$z = \frac{1}{a} \ln \left(c - \frac{\Delta F}{kRT} \right) + \frac{b}{a} \quad (14)$$

The equations developed can be combined to give a three-dimensional figure as shown in Fig. 2. The model for this photograph was constructed

Fig. 2 —The systematic change in the dissociation constant of the acids as the substituting radical is moved varying distances, measured by number of intervening CH_2 units, from the carboxyl group

to scale from the equations already given, the location of the substituents R along the x -axis is the same as that in Fig. 1 and in fact the curve in the

¹² See discussion regarding this treatment under the heading, Surface Tension as a Measure of Polarity.

$x\gamma$ plane and the two succeeding curves are the same as those shown in Fig. 1 for the relationship between the dissociation constants of RCOOH , RCH_2COOH and $\text{RCH}_2\text{CH}_2\text{COOH}$. The only outstanding abnormality found so far is that of formic acid or the point where $\text{R} = \text{H}$. From the comparison between the homologous series of alkyl acids and amines given below, this would appear to be the characteristic "abnormality of the first member of the series." This is treated later.

From the mathematical relationship previously pointed out for the dissociation constants of the acids and amines, it would be expected that a plane similar to that shown in Fig. 2 for the dissociation constants of the acids could also be constructed for the corresponding amines.

Fig. 3.—The similarity of the effect of intervening CH_2 units on the dissociation constants of corresponding acids and amines.

In fact the curves given in Fig. 1 for the two series RNH_2 and RCOOH would show the intersection of these surfaces with the $x\gamma$ plane. Unfortunately, data are not available for checking this conclusion over any extended range. However, the similarity of the change between the dissociation constants of the acids and amines as CH_2 units are interposed between R and the polar group is apparent from a comparison of the following pairs of equations for $\log K$ of

- (a) the alkyl amines $\text{H}(\text{CH}_2)_z\text{NH}_2$ $\log K = -20(e^{-1.6z-2.57} + 0.16)$
 the alkyl acids $\text{H}(\text{CH}_2)_z\text{COOH}$ $\log K = 20(e^{-1.6z-2.6} - 0.25)$
 (b) the alkyl diamines $\text{H}_2\text{N}(\text{CH}_2)_z\text{NH}_2$ $\log K = -20(e^{0.6z-2.05} + 0.15)$
 the alkyl diacids $\text{HOOC}(\text{CH}_2)_z\text{COOH}$ $\log K = 20(e^{0.6z-1.61} - 0.25)$

The similarity is more clearly seen by comparing the two pairs of curves in Fig. 3 for these equations. The agreement between the measured and calculated values is given in Table III for all except the alkyl acids, which were given in Table II.

OBSERVED AND CALCULATED VALUES FOR $-\log K$ OF SOME AMINES AND ACIDS

together in Table IV for comparison of effect of relative position. A perspective drawing is shown in Fig. 4, the substituting groups being spaced as to their electron-sharing ability on the same scale as in Figs. 1 and 2. The *ortho*, *meta* and *para* positions are plotted along the *z*-axis as of equal distance from the polar group, for the lack of any other standard. In spite of the rather large experimental error involved in the determination of these values, the only outstanding discrepancy is the value for the *p*-methylcarboxylic-substituted aniline.

Surface Tension as a Measure of Polarity.—The work of Langmuir¹⁸ regarding the structure of adsorbed films on the surface of liquids supports the generalizations advanced in this paper. After showing that the polar group causes orientation of the molecule in the surface film formed by an insoluble body on water, he calculated from Traube's data for the surface tensions of aqueous solutions of organic compounds, the loss in potential energy λ , when a gram molecule of the solute passes from the interior to the surface of the solution. Quoting from Langmuir, "... λ can be expressed in general by an equation of the form $\lambda_{\text{cal}} = \lambda_0 + 625 n$, where n is the number of carbon atoms in the molecule. The quantity λ_0 has a different value for each type of substance as is shown in Table V."

TABLE V
VALUES OF λ_0 GIVEN BY LANGMUIR

Type	Formula	λ_0	Type	Formula	λ_0
Tertiary alcohol	$R_3\text{COH}$	950	Ketone	RCOR'	295
Primary amine	RCH_2NH_2	600	Aldehyde	RCHO	210
Primary alcohol	RCH_2OH	575	Amide	RCONH_2	-510
Ester	RCOOR'	470	Dibasic acid (or alcohol)	..	-700
Monobasic acid	RCOOH	437			

In other words, the change for each intervening CH_2 unit is a constant, namely 625 calories, or all CH_2 units are equivalent. This would be the justification for treating the intervening CH_2 units as a measure of distance, as was done in Fig. 2.

A strict interpretation of Langmuir's equation implies that if λ were obtained for a number of radicals and plotted against intervening CH_2 units, as was done in Fig. 2 for the dissociation constants of the acids, a series of parallel planes would be obtained for all polar groups. It should be pointed out that the data available to Langmuir were limited almost entirely to the aliphatic compounds or, referring to Fig. 2, to that field in which there is little change in the potential of the polar group as CH_2 units are interposed between it and the radical R. If the orientation of the molecule is a function of the polar group, as Langmuir's work indicates, $\Delta\lambda$ for any homologous series would not be a constant unless the potential of this group remained unchanged as CH_2 units were inter-

¹⁸ Langmuir, *THIS JOURNAL*, 39, 1848 (1917).

posed. In Langmuir's data, there are only two series in which this can be checked, but both of these substantiate this modification of Langmuir's equation (see Table VI).

TABLE VI

COMPARISON OF THE POLARITY OF THE CARBOXYL GROUP AS MEASURED BY THE DISSOCIATION CONSTANT, AND THE EQUIVALENCE OF ALL CH_2 UNITS AS INDICATED BY LANGMUIR'S SURFACE-TENSION STUDY

Substance	Intervening CH_2 units	$-\log K$	Obs	$\Delta\lambda^a$
HCOOH	0	3.67	1078	632
HCH_2COOH	1	4.73	1710	
$\text{H}(\text{CH}_2)_2\text{COOH}$	2	4.83	2290	
$\text{H}(\text{CH}_2)_3\text{COOH}$	3	4.80	2910	580
HOOCCOOH	0	1.00	516	764
$\text{HOOC}(\text{CH}_2)\text{COOH}$	1	2.78	1280	
$\text{HOOC}(\text{CH}_2)_2\text{COOH}$	2	4.17	1510	230

^a This should be a constant equal to 625 calories, according to Langmuir's equation

If this limitation of Langmuir's generalization is found to hold over an extended range, it should offer an experimental means of explaining the discrepancies of the first member of each homologous series. It should be pointed out that our present theories of valence imply that affinity is a function of potential and structure only, the quantity factor entering only as multiple units. The application of any form of electrostatics indicates that such would not be the case and offers the best explanation for these "exceptions."

Summary

It is pointed out that if the electron theory of valence holds, the properties of any polar group must be a function of the "electron-sharing ability" of the radical or element to which it is linked. The available data are collected and the mathematical relationship is pointed out between the dissociation constants and free energy of ionization of the series $\text{R}(\text{NH}_2)$, $\text{R}(\text{COOH})$, $\text{R}(\text{CH}_2\text{COOH})$, $\text{R}(\text{CH}_2\text{CH}_2\text{COOH})$ and $\text{R}(\text{OH})$. It is also pointed out that an exponential equation of the same general form holds for the change in the dissociation constant as intervening CH_2 units are introduced. Theories of structure have been intentionally avoided since the mathematical relationships will hold, independent of the mechanical interpretations which may be advanced in explanation of them.

POSITIVE HALOGENS ATTACHED TO CARBON IN THE AROMATIC SERIES. II. IODINE DERIVATIVES OF META-PHENYLENEDIAMINE AND OF RESORCINOL

BY BEN H. NICOLET AND JOHN R. SAMPEY¹

RECEIVED MARCH 26, 1927

PUBLISHED JULY 5, 1927

Some time ago one of us² called attention to the fact that certain compounds containing bromine or iodine in the benzene ring could undergo hydrolysis in such a way that the halogen was replaced by hydrogen, while the solution acquired oxidizing properties evidenced by the liberation of free halogen, or by the formation of more highly halogenated derivatives. Such behavior might be said to constitute the experimental definition of what is here meant by a positive³ halogen in organic combination.

In the cases previously cited, the halogen which reacted in this manner was always *ortho* or *para* to an amino or hydroxyl group. As these radicals are among the most strongly negative recognized by advocates of modern theories of polar valence⁴ as applied to organic compounds, the results are well in accord with those to be deduced from the electronic structure of benzene as depicted by Stieglitz⁵ or from the theory of induced alternations in polarity.^{6,7} As a further consequence of these theories

¹ The material here presented was used by John R. Sampey in partial satisfaction of the requirements for the degree of Doctor of Philosophy at the University of Chicago, 1923.

² Nicolet, *THIS JOURNAL*, **43**, 2081 (1921).

³ A *relatively* positive halogen (as shown by its reactions) is meant. The "assumption that each atom in a molecule exists in a definite oxidation-reduction stage which can be represented by an integral polar number" [Lewis, "Valence and the Structure of Atoms," A. C. S. Monograph Series, Chemical Catalog Co., New York, 1923] is here expressly denied. A displacement, probably relatively slight, of the electrons which in terms of the Lewis theory are shared by the atoms in question, could explain the results here described.

⁷ It seems of interest to point out that since substituents entering the benzene ring are usually positive (Ref. 5) the data collected by de Lange [*Rec. trav. chim.*, **45**, 19 (1926)] on "The Displacement of Atoms and Groups in the Benzene Nucleus," can in general be interpreted as the replacement of *positive* groups. It will be shown in Paper V of the present series [Nicolet, *THIS JOURNAL*, **49**, 1810 (1927)] that the existence of reactions by which these polarities can be demonstrated may also be correlated with the possibility of the formation of quinoidal derivatives. Whatever the ultimate fate of the present interpretation may be, at the very least it constitutes a conspicuously efficient mnemonic system for the prediction of such replacements.

and of the interpretation previously given, it was to be expected that two amino or hydroxyl groups, both *ortho* or *para* to the halogens in question, would result in increased reactivity of these halogens in the sense indicated. It is the purpose of this paper to show that suitable iodo derivatives of *m*-phenylenediamine and of resorcinol behave in the anticipated manner.

The preparation of the necessary derivatives, a number of which are new, is described in the Experimental Part. All of them showed liberation of iodine when boiled with 10% hydrochloric acid, the rates varying both with constitution and with the solubilities of the individual substances. It was not thought desirable to estimate quantitatively the rates of iodine liberation, as these were obviously complicated by simultaneous reactions of resubstitution and of oxidation. While the *type* of these side reactions confirms the assumption that halogen is here removed in positive form, their *existence* would make useless any figures on rate of accumulation of oxidizing substances in solution. The type of initial reaction assumed is here indicated.

Data are presented showing relative rates of formation of iodide ion when the substances described are boiled with acid in the presence of sufficient acetic acid to dissolve them, and of an excess of stannous chloride, to prevent oxidation and resubstitution. The use of stannous chloride in the estimation of the positivity of halogens under such conditions has already been suggested.¹ Experience seems to have justified its use.⁸ The use of hydriodic acid as reducing agent in such tests has recently become somewhat common.⁹ While we are inclined to believe that the rate of removal of halogen atoms by reduction with hydriodic acid is probably related to the positivity of the halogen in question, there are few halogens which are not replaced by hydrogen under the influence of hydriodic acid at higher temperatures;¹⁰ there is also the further disturbing factor, particularly in the work quoted,⁹ that the reaction¹¹

⁸ Three lines of evidence may be mentioned. (a) The halogens removed, as recorded in chemical literature and as found in these experiments, are those, and only those, whose removal would be predicted on the basis of the theory here presented. (b) No evidence is known that stannous chloride can act like certain metals (in other words, magnesium in the Grignard reagents) to form an intermediate compound of a type which would be expected to hydrolyze in such a way as to give the results obtained. Burton and Kenner [*J. Chem. Soc.*, 121, 680 (1922)] suggest the formation of an intermediate compound which they assume would act in this way; we doubt their interpretation, for reasons given in this note, particularly under (c). (c) In certain analogous cases, evidence has been obtained (as yet unpublished) that the *rate* of removal of halogen is not proportional to the concentration of stannous chloride present.

⁹ Ref. 6 d. Shoesmith, *J. Chem. Soc.*, 123, 2828 (1923). Ref. 4 c.

¹⁰ Klages, *J. prakt. Chem.*, [2] 61, 307 (1900).

¹¹ Conant, Kirner and Hussey, *THIS JOURNAL*, 47, 488 (1925), and earlier papers there cited.

$\text{RBr} + \text{HI} = \text{RI} + \text{HBr}$ continually changes, to an uncontrolled extent, the nature of the halogen being removed. We are, therefore, much inclined to prefer stannous chloride as a diagnostic reagent. Its rather extreme specificity will be further illustrated in Paper IV of this series.

Experimental Part

4-Iodoresorcinol.¹²—It was not found possible to prepare this substance by the method of Stenhouse.¹³ Several attempts to modify his conditions led also to mixtures in which, after benzylation, it was possible to identify only derivatives of resorcinol and di-iodoresorcinol. The action of iodine chloride in ether, acetic acid or hydrochloric acid gave similar results. Attempts to obtain it from 5-iodo-2,4-dihydroxybenzoic acid or from 4-iodo-3-hydroxyphenyl benzoate also failed. Finally, mono-mercurized resorcinol was prepared by the method of Dimroth;¹⁴ the yield was very poor. Replacement of the mercury by iodine took place normally, and Stenhouse's 4-iodoresorcinol¹⁵ resulted.

4,6-Di-iodoresorcinol.—To 5 g. of resorcinol dissolved in 185 cc. of 20% hydrochloric acid was added 7.3 g (2 moles) of iodine monochloride. A precipitate appeared immediately. After fifteen minutes, the excess of iodine was removed with sodium sulfite, the solution filtered, and the solid dried and crystallized from benzene; yield, 80%. The substance forms colorless crystals, m. p. 145°, readily soluble in ether, alcohol and benzene, less so in chloroform and hot water, and nearly insoluble in cold water and ligroin.

Anal. (Carius). Calcd. for $\text{C}_6\text{H}_4\text{O}_2\text{I}_2$: I, 70.1. Found: 69.9.

The same substance was also made by the method of Stenhouse¹³ but a pure product was more difficult to obtain by this procedure.

4,6-Di-iododibenzoylresorcinol.—The di-iodoresorcinol was dissolved in 10% sodium hydroxide solution, and benzyolated by the Schotten-Baumann method. The product decomposed at 195–200°.

Anal. (Carius). Calcd. for $\text{C}_{20}\text{H}_{12}\text{O}_4\text{I}_2$: I, 44.6. Found: 45.0.

4-Iodo-3-hydroxyphenyl Benzoate.—Monobenzoylresorcinol¹⁶ was dissolved in glacial acetic acid, and treated with 1 mole of iodine chloride in the same solvent, avoiding rise in temperature. After 15 minutes water was added and the excess of iodine was removed with sodium sulfite. The insoluble material (yield, 65%) was crystallized from benzene. It decomposed at 153–155°.

Anal. (Rosanoff).¹⁷ Calcd. for $\text{C}_{13}\text{H}_9\text{O}_3\text{I}$: I, 37.3. Found: 37.4.

5-Iodo-2,4-dihydroxybenzoic Acid.—Resorcinic acid¹⁸ was iodinated with one mole

¹² No proof is here offered as to the positions assigned to iodine in the products described. The structures given seem logical and further work in progress appears likely to confirm them.

¹³ Stenhouse, *Ann.*, **171**, 311 (1874).

¹⁴ Dimroth, *Ber.*, **35**, 2865 (1902).

¹⁵ Richter, "Lexikon der Kohlenstoff-Verbindungen" gives 167° as the melting point of this substance. That given by Stenhouse (67°) is correct.

¹⁶ Kauffmann and Kugel, *Ber.*, **44**, 753 (1911).

¹⁷ Drogin and Rosanoff, *THIS JOURNAL*, **38**, 711 (1916).

¹⁸ Bistrzycki and Kostanecki, *Ber.*, **18**, 1984 (1855).

of iodine monochloride in ether solution. The product (yield, 44%), after crystallization from dilute acetone, melted at 172°. Attempts to prepare it by the method of Stenhouse¹³ gave a mixture of mono- and di-iodinated acids.

Anal. (Carius). Calcd. for $C_7H_5O_4I$: I, 45.4. Found: 45.7.

3,5-Di-iodo-2,4-dihydroxybenzoic Acid.—To a solution of 11 g. of resorcinic acid and 36 g. (2 equivalents) of iodine in 100 cc. of ether, was added 75 g. of litharge, and the whole was refluxed for two hours. After evaporation of the ether, the residue was extracted with alcoholic alkali, and the crude di-iodo acid recovered from the extract by dilution with water, acidification and treatment with sodium sulfite; yield, 50%. The product decomposed at 193–196°.

Anal. (Carius). Calcd. for $C_7H_3O_4I_2$: I, 62.3. Found: 62.9.

4-Chloro-6-iodo-*m*-phenylenediamine.—4-Chloro-*m*-phenylenediamine was iodinated in cold, absolute methyl alcohol solution with 1 mole of iodine and an excess of litharge. After three hours, the solution was filtered, the residue washed with methyl alcohol and the product recovered from the combined filtrates by dilution with water; yield, 80%; m. p., 98°.

Anal. (Carius). Calcd. for $C_6H_6N_2ClI$: AgCl, AgI, 140.2. Found: 139.9.

The same substance was obtained by refluxing a mixture of the chlorodiamine and iodine with water, ether and calcium carbonate. The yield, however, was less good. Iodination with iodine monochloride was unsatisfactory, as oxidation of the amine occurred.

4-Iododiacetyl-*m*-phenylenediamine.—*m*-Nitro-acetanilide was reduced with iron and acetic acid.¹⁹ The solution was filtered from the excess of iron and tarry impurities before making alkaline with sodium carbonate. After salting out and filtering, repeated extraction of the solid with hot benzene gave 70% of the calculated quantity of *m*-amino-acetanilide. Into 5 g. of this, dissolved in 200 cc. of 5% hydrochloric acid, was slowly aspirated 4.9 g. (1 mole) of iodine chloride as vapor. The crude iodo-mono-acetyldiamine was dried, and triturated in a mortar with 2 g. of fused sodium acetate and 3 cc. of acetic anhydride, to form the diacetyl derivative. After crystallization from benzene and from chloroform, the 4-iododiacetyl-*m*-phenylenediamine decomposed at 175–180°.

Anal. (Carius). Calcd. for $C_{10}H_{11}O_2N_2I$: I, 35.5. Found: 36.0.

4,6-Di-iodo-3-acetylamino-aniline.—Four g. of *m*-amino-acetanilide was dissolved in 200 cc. of warm 10% hydrochloric acid, and 8 g. (2 equivalents) of iodine chloride was added. After 15 minutes, sodium sulfite was added to remove the excess of iodine and then sufficient caustic alkali to liberate the amine. The product, crystallized from methyl alcohol, melted at 172–174°.

Anal. (Carius). Calcd. for $C_8H_8ON_2I_2$: I, 60.6. Found: 60.5.

Method of Hydrolysis and Analysis.—All of the substances which have been described liberate iodine when boiled with hydrochloric acid. Some, however, are only slightly soluble in this reagent. Moreover, the iodine liberated causes variable amounts of resubstitution and of oxidation. It was therefore decided to measure the reactivity of iodine in the respective substances by adding sufficient acetic acid to bring them into solution and also an excess of stannous chloride to remove the liberated iodine (as iodide ion) from further reaction. The procedure was as follows.

¹⁹ By the method used for the *para* compound by Nietzki, *Ber.*, 17, 343 (1884).

The halogen compound (0.125 g) was dissolved in 10 cc. of hot glacial acetic acid. To this solution, heated in a bath of boiling water, was added 5 cc. of a hot solution containing 10% each of hydrochloric acid and of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$. Heating was then continued for the time desired, and the solution was removed from the bath, rapidly cooled in water, and analyzed for iodide.

The analytical procedure was based on a method of Fresenius²⁰ and may be thus outlined.

To the sample to be analyzed, 15 cc. of chloroform was added. Then a 10% solution of sodium nitrite was added, drop by drop, with thorough mixing until the chloroform layer began to be colored; an additional 0.5 cc was then added; the chloroform was separated and the solution extracted with two more 15cc. portions of chloroform. The combined chloroform extracts were then washed with several small portions of water. After the addition of a few drops of sodium bicarbonate solution, the iodine in the chloroform layer was titrated with 0.02 *N* sodium thiosulfate solution. Special tests in each case showed that the action of nitrous acid under the conditions described did not liberate disturbing amounts of iodine from any of the organic substances used

TABLE I
RELATIVE RATES OF IODINE REPLACEMENT

Compound used	Time of reaction, minutes	Total iodine removed, %
4-Iodoresorcinol	5	87
4,6-Di-iodoresorcinol	7	66.8
	7	66.5
4-Iodo-3-hydroxyphenyl benzoate	30	11.6
	60	20.0
4,6-Di-iododibenzoylresorcinol	60	2.5
	60	2.7
5-Iodo-2,4-dihydroxybenzoic acid	30	42.4
3,5-Di-iodo-2,4-dihydroxybenzoic acid	30	39.8
4-Iodo- <i>m</i> -phenylenediamine ^a	5	66.8
	5	66.0
4,6-Di-iodo- <i>m</i> -phenylenediamine ^{a,b}	5	86.6
	5	85.5
4-Iododiacetyl- <i>m</i> -phenylenediamine	20	66.0
4-Iodo-6-chloro- <i>m</i> -phenylenediamine	5	98.0
	5	97.5
2-Iodo- <i>p</i> -phenylenediamine ^c	60	25.6
	60	25.2
3-Iodo-4-aminotoluene	30	22.0

^a The corresponding acetyl derivatives were heated for two hours with an excess of 3% sodium hydroxide in 80% alcohol, and the solution was filtered hot to remove a small amount of tar. Water was then added and the alcohol removed by distillation. After cooling, white crystals remained which were separated and dried.

^b Morgan and Wootton [*J. Chem. Soc.*, **87**, 938 (1905)] have described this substance. They found it rather unstable, and state that "the hydrochloride is decomposed by boiling water."

^c We are indebted to Dr. W. L. Ray for a sample of this compound.

²⁰ Treadwell and Hall, "Analytical Chemistry," John Wiley and Sons, New York, vol. 2, 1919, p. 657.

Relative Ease of Removal of Iodine.—The conditions used have been described. Table I gives the percentage of total iodine present removed after heating at 100° for the lengths of time specified.

Summary

1. The preparation of a number of new iodo derivatives of resorcinol and of *m*-phenylenediamine has been described.
2. A standard method for the removal of iodine from these substances by hydrolysis and mild reduction has been applied and the results have been correlated with the theory presented as to the relatively positive nature of the halogens involved.

POSITIVE HALOGENS ATTACHED TO CARBON IN THE AROMATIC SERIES. III. DERIVATIVES OF PARA-PHENYLENEDIAMINE, PARA-NITRO-ANILINE AND MESITYLENE

BY BEN H. NICOLET AND WILLIAM L. RAY¹

RECEIVED MARCH 26, 1927

PUBLISHED JULY 5, 1927

As has been more clearly set forth in previous papers² a positive character is attributed to such halogens as are removed on hydrolysis to give products other than halides, and are replaced during this reaction by hydrogen. Such behavior has been demonstrated in the case of a number of *o*- or *p*-bromo or iodo derivatives of phenol and of aniline, and corresponding iodo derivatives of resorcinol and of *m*-phenylenediamine have been shown to give similar results with the greater readiness which would be expected if the two negative groups united in enforcing an increased positivity of the halogens in question.

Before reporting the work done with derivatives of *p*-phenylenediamine and *p*-nitro-aniline, some results obtained with iodomesitylene will be discussed briefly. The methyl group is usually considered to be negative, although conspicuously less so than the hydroxyl or amino group. A sufficient number of methyl groups, properly placed, might perhaps cause an iodine atom to show properties similar to those referred to above. The ideal derivative for such a purpose should be iodomesitylene,³ which

¹ The material here presented was used by William L. Ray in partial satisfaction of the requirements for the degree of Doctor of Philosophy at the University of Chicago, 1923.

² (a) Nicolet, *THIS JOURNAL*, **43**, 2081 (1921). (b) Nicolet and Sampcy, *ibid*, **49**, 1796 (1927).

³ Klages [*J. prakt. Chem.*, [2] **61**, 307 (1900)] has shown that iodomesitylene is reduced by hydriodic acid at a considerably lower temperature than that required for iodobenzene. Töhl and Eckel [*Ber.*, **26**, 1099 (1893)] found that iodomesitylene yielded

contains three methyl groups, all *ortho* or *para* to the iodine in question. It was found that while a solution of iodomesitylene in glacial acetic acid containing hydrogen chloride could be heated under reflux without the liberation of appreciable quantities of iodine, such solutions, when heated in sealed tubes at 135 or 150°, showed iodine liberation to a very considerable extent. Under similar conditions phenyl iodide showed, as was expected, no evidence of reaction.

Preparation and Hydrolysis of Iodomesitylene.—The iodination of mesitylene with iodine and iodic acid in acetic acid solution⁴ gave better results than the use of sulfur iodide.⁵ Owing to the insolubility of iodomesitylene in water, a solution was prepared containing, per 100 cc. of glacial acetic acid, 5.6 g. of iodomesitylene and 6.6 g. of dry hydrogen chloride. Portions of this solution were heated in sealed tubes in a bomb furnace with the results shown in Table I. The liberated iodine was titrated with thiosulfate, and unaltered iodomesitylene was recovered in each case. After the last run no di-iodomesitylene could be found, showing that resubstitution had not occurred to any appreciable extent. Mesitylene was, however, isolated and identified by its boiling point and by the deep red color it gave with diazotized picramide.⁶

TABLE I
LIBERATION OF IODINE FROM IODOMESITYLENE

Time of heating, hours	Temp., °C.	Total iodine liberated, %
1	135	7.8
1	135	9.5
4.5	150	20.0
6	150	42.9

Iodobenzene was heated under conditions parallel to those described. No iodine color developed and no benzene could be detected.

A solution of 2 g. of iodomesitylene and 3.66 g. (2 molecular proportions) of stannous chloride in 7.2 cc. of concd. hydrochloric acid and 34 cc. of acetic acid was heated for 6.5 hours at 135°. The chief product was mesitylene, although a little of the iodo derivative remained.

As a test of the theory as to the importance of the position occupied by the activating groups, as well as of their number and character, it was considered desirable to study the effect on the lability of a bromine or iodine atom in the 2 position relative to an amino group, of additional substituents such as an amino or a nitro group in the 4 position. To this end, suitable derivatives of *p*-nitro-aniline and of *p*-phenylenediamine were prepared and characterized.

di-iodomesitylene when shaken with concd. sulfuric acid. The latter is, however, too strong an oxidizing agent to make this resubstitution conclusive evidence of positivity.^{2a}

⁶ Meyer and Tochtermann, *Ber.*, 54, 2283 (1921).

Hydrolyses with Acid Only.—Solutions of the substance in 10% hydrochloric acid were boiled under reflux for suitable periods. After appropriate adjustment of the acidity, these solutions were then titrated with thiosulfate. The results obtained with 2-iodo-4-nitro-aniline are given in Table II, with velocity constants (time in minutes) calculated for a first-order reaction.

TABLE II
HYDROLYSIS OF 2-iodo-4-NITRO-ANILINE WITH ACID ONLY

Time, min.	Reaction, %	$K \times 10^3$
120	27.6	2.69
205	45.7	2.98
240	51.2	2.99
360	63.3	2.82

The "constants" obtained by this method have, however, relatively little meaning and are given only to illustrate this fact. The accumulation of oxidizing power in the solution (which is what is measured) really represents the difference between hydrolysis on the one hand and resubstitution or oxidations of other types on the other. In the case of iodophenylenediamine, extensive oxidation was evident from the first and the values found were very irregular. With iodonitro-aniline no destructive oxidation was noticed. The extent to which resubstitution took place is unknown, at least no di-iodonitro-aniline could be detected under the conditions described. When, however, iodonitro-aniline was heated under reflux with three parts of glacial acetic acid and one of hydrochloric acid, some 2,6-di-iodo-4-nitro-aniline (m. p., 243°) was isolated, and when 2 g. of the iodonitro-aniline was heated with 20 cc. of concd. hydrochloric acid in a bomb tube for eight hours at 105° , not only was some of the di-iodo derivative formed, but the resulting solution showed very little oxidizing power. In view of the other results described, there can be little question that hydrolysis was here a fairly rapid reaction, but resubstitution must have taken place with almost equal efficiency. The reason for placing little weight on quantitative results obtained in the presence of acid alone is thus apparent.

Hydrolyses in the Presence of Stannous Chloride.—This more accurate method cannot, of course, be applied to nitro compounds, as they would undergo reduction. In making measurements, 2 g. of substance was dissolved in 20 cc. of 10% hydrochloric acid containing 4.0 g. of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$. Such solutions were boiled under reflux for the desired periods, and then cooled. Iodine was determined as described by Nicolet and Sampey.^{2b} The results obtained with 2-iodo-*p*-phenylenediamine are given in Table III, together with the velocity constants calculated on the assumption⁷ that the reaction rate is proportional only to the concentration of the

⁷ For a justification of this assumption, see Ref. 2b.

organic iodo compound. For comparison, *o*-iodo-aniline was prepared and hydrolyzed under parallel conditions. The percentage of reaction after 15 and 30 minutes was in this case 61.9 and 89.0%, corresponding to $K \times 10^3 = 64.0$ and 74.0, respectively. It is apparent that the 4-amino group decreases the rate of reaction decidedly.

TABLE III
HYDROLYSIS OF IODO-*p*-PHENYLENEDIAMINE, USING STANNOUS CHLORIDE

Time, min.	Total iodine removed, %	$K \times 10^3$, min.
60	29.4	5.9
180	72.9	7.2
240	79.4	7.1
300	89.5	7.5

The hydrolysis of bromo-*p*-phenylenediamine was similarly carried out in the presence of stannous chloride, but the direct determination of small quantities of bromine in the resulting solutions offered too great difficulties, and the progress of reaction was followed in a somewhat rough manner as follows.

After heating for the desired lengths of time, the solutions were cooled, treated with an excess of sodium acetate to remove free hydrochloric acid and then well shaken with 25 cc. of acetic anhydride. The precipitates, consisting of a mixture of the diacetyl derivatives of *p*-phenylenediamine and its bromo derivative, with base tin salts, were collected, and the tin salts washed out with dil. hydrochloric acid. Bromine was then determined (Carius) in the residue, and the proportion of the bromo compound calculated. As diacetyl *p*-phenylenediamine is decidedly less soluble than its bromo derivative, this method somewhat exaggerates the ease of bromine removal. After boiling for six and nine hours the extent of bromine removal was found to be 54.3 and 78.8%, corresponding to values of $K \times 10^3$ (minutes) of 2.3 and 2.9, respectively. As anticipated, bromine is removed less rapidly than iodine.

Experimental Part

2-Iodo-*p*-phenylenediamine.—Ten g. of 2-iodo-4-nitro-aniline⁸ was covered with 50 cc. of concd. hydrochloric acid and gently warmed, and 30 g. of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ in 50 cc. of hydrochloric acid was added slowly with stirring. Stirring and warming were continued until most of the material was dissolved and the yellow color had disappeared. The solution was cooled in ice (a white double salt separated) and cautiously made alkaline with 50% sodium hydroxide solution. After thorough cooling, rapid filtration gave a 75% yield of product which crystallized from water in white needles; m. p., 110.5°.

Anal. (Carius). Calcd. for $\text{C}_6\text{H}_7\text{N}_2\text{I}$: I, 54.24. Found: 54.03, 53.93.

2,5-Diacetyl-amino-iodobenzene.—This was readily obtained by the action of acetic anhydride and crystallized from acetic acid; m. p., 211.5°.

Anal. (Carius). Calcd. for $\text{C}_{10}\text{H}_{11}\text{O}_2\text{N}_2\text{I}$: I, 39.91. Found: 39.80.

2,5-Dibenzoylamino-iodobenzene.—The base was benzoylated by the Schotten-Baumann method. The product, slightly soluble in the commoner solvents, was crystallized from nitrobenzene; m. p., 254°.

⁸ Willgerodt and Arnold, *Ber.*, **34**, 3351 (1901).

Anal. (Carius). Calcd. for $C_{20}H_{16}O_2N_2I$: I, 28.71. Found: 28.86.

Acetylation of 2,6-Di-iodo-4-nitro-aniline.—Körner and Contardi⁹ reported an acetyl derivative melting at 249°, prepared by the action of acetic anhydride on the amine. When the base was refluxed for an hour with an excess of anhydride, with or without fused sodium acetate, we obtained a product melting at 248°, which was only exceptionally pure di-iodonitro-aniline.

Anal. (Carius). Calcd. for $C_8H_4O_2N_2I_2$: I, 65.11. Found: 64.97.

When 10 g. of the base was warmed with 35 cc. of anhydride containing five drops of concd. sulfuric acid, the *N*-diacetyl derivative melting at 169°¹⁰ was formed.

Anal. (Carius). Calcd. for $C_{10}H_8O_4N_2I_2$: I, 53.55. Found: 53.40, 53.45.

2-Bromo-4-nitro-aniline.—This substance has been made by a number of indirect methods.¹¹ The direct bromination has been stated⁹ to give a mixture difficult to separate, of mono- and dibromo derivatives. The following procedure was found effective. Seventy-five g. of *p*-nitro-aniline was dissolved by heating in 1000 cc. of concd. hydrochloric acid and the solution rapidly cooled to room temperature. The aspiration through the solution of 87 g. of bromine was begun promptly and completed during two hours with frequent agitation. The solution was then filtered and the solid agitated with a liter of water to hydrolyze the hydrochloride. The insoluble base was crystallized from 600 cc. of 65% alcohol. The yield, including two crops after concentration of the solution, was 81%; m. p., 104.5°. When the bromine was dissolved in concd. hydrochloric acid and added in this form, the yield was reduced and some of the dibromo derivative was formed.

2-Bromo-4-nitro-acetanilide.—Attempts to brominate *p*-nitro-acetanilide in acetic acid solution were not successful even when iron wire was added as catalyst. Acetylation of bromonitro aniline is moderately difficult. Chattaway and Orton¹² heated it with acetyl chloride at 130° and obtained a mono-acetyl derivative melting at 129°, but Körner and Contardi⁹ speak of an acetyl derivative (m. p., 114°) and a diacetyl derivative (m. p., 132°). To a mixture of 10 g. of bromonitro-aniline and 5 cc. of glacial acetic acid containing 5 drops of concd. sulfuric acid, was added 5 cc. of acetic anhydride and the whole was warmed until the yellow color disappeared. The nearly white product (10.5 g.) melted at 129–130°. It was also obtained when the base was boiled for an hour with acetic anhydride alone. Analysis showed it to be the mono-acetyl derivative.

2-Bromo-*p*-phenylenediamine.—The bromonitro-aniline was reduced as already described for the iodo compound, and the base extracted with ether. The product (yield, 75%) crystallized from carbon tetrachloride in white needles; m. p., 76°.

Anal. (Carius). Calcd. for $C_6H_7N_2Br$: Br, 42.73. Found: 42.86, 42.95.

2,5-Diacetylaminobromobenzene.—The acetylation offered no difficulty. The product melted at 200°.

Anal. (Carius). Calcd. for $C_{10}H_{11}O_2N_2Br$: Br, 29.48. Found: 29.61.

2-Bromo-4-amino-acetanilide.—Bromonitro-acetanilide was suspended in twice its weight of concd. hydrochloric acid and treated with 3 moles of $SnCl_2 \cdot 2H_2O$ in the same solvent. The mixture, which became somewhat warm, was stirred for half an hour, cooled and made alkaline with 50% sodium hydroxide solution. The gummy mass which separated gave crystals from benzene; m. p., 123°.

⁹ Körner and Contardi, *Atti accad. Lincei*, 22 [I], 825 (1913); *C. A.*, 8, 73 (1914).

¹⁰ Körner and Contardi (Ref. 9) give 171°.

¹¹ Hübner, *Ber.*, 10, 1709 (1877); *Jahresber.*, 305, 350, 1875, Ref. 9.

¹² Chattaway and Orton, *Ber.*, 33, 2398 (1900).

Anal. (Carius). Calcd. for $C_8H_9ON_2Br$: Br, 34.89. Found: 35.26, 35.36.

2,3,5-Tribromo-4-amino-acetanilide.—When 2.6 g. (2 molecular proportions) of bromine was aspirated into a solution of 2 g. of 3-bromo-4-amino-acetanilide in 50 cc. of glacial acetic acid, a solid tribromo derivative separated. After being treated with alkali to remove hydrobromic acid and crystallized from alcohol, it formed white needles; m. p., 207°. Smaller amounts of bromine gave the same product but in smaller yields.

Anal. (Carius). Calcd. for $C_8H_7O_2N_2Br_3$: Br, 61.97. Found: 61.99, 61.86.

The structure assigned is the one that would be expected from the method of preparation. By diazotization and reduction, the amino group was replaced by hydrogen. Hydrolysis of the product gave a substance melting somewhat indefinitely from 88 to 90°. The expected product, 2,3,5-tribromo-aniline, melts at 91°.¹³

Summary

1. Some new bromo and iodo derivatives of *p*-phenylenediamine have been described.

2. Determinations of the rate of halogen removal from *o*-iodo-aniline and from iodo- and bromo-*p*-phenylenediamine, under conditions designed to measure the positivity of the halogen in question, gave results in the ratio 69.0:6.9:2.6. These fall in the order predicted by the theory advanced.

POSITIVE HALOGENS ATTACHED TO CARBON IN THE AROMATIC SERIES. IV. SELECTIVITY OF HALOGEN REMOVAL

BY BEN H. NICOLET AND REUBEN B. SANDIN¹

RECEIVED MARCH 26, 1927

PUBLISHED JULY 5, 1927

In previous papers of this series² attention has been called to the tendency of bromine or iodine occupying certain specific positions in aromatic compounds to be removed by hydrolysis and replaced by hydrogen. Such halogens are to be found primarily in positions *ortho* or *para* to amino or hydroxyl groups, and their whole behavior is conveniently summed up in the statement that they react as somewhat positive halogens.

In studying the removal of such halogens it has often proved more convenient to perform the hydrolysis in the presence of stannous chloride in order to obviate effects due to resubstitution and to oxidation. It is believed that the presence of this reducing agent does not affect in any important way the primary reaction of halogen removal.^{2b}

¹³ Claus and Wallbaum, *J. prakt. Chem.*, [2] 56, 60 (1897).

¹ The material here presented was used by Reuben B. Sandin in partial satisfaction of the requirements for the degree of Doctor of Philosophy at the University of Chicago, 1924.

² (a) Nicolet, *THIS JOURNAL*, 43, 2081 (1921). (b) Nicolet and Sampey, *ibid.*, 49, 1796 (1927). (c) Nicolet and Ray, *ibid.*, 49, 1801 (1927).

The explanation advanced for the behavior of these reactive halogens implies that halogens in other positions in the molecule should show very different behavior and there is a large amount of evidence in the chemical literature to show that this is, at least qualitatively, the case. In the present paper, striking evidence of a more quantitative nature is presented.

3-Iodo-4-aminotoluene readily shows the reactions of positive iodine.^{2a,3} 2-Iodo-4-aminotoluene should not and, we find, does not show such reactions. A number of new derivatives of the latter substance, containing bromine or iodine in the 3 or 5 position, have been prepared and their hydrolysis with hydrochloric acid in the presence of stannous chloride has been studied. The results (Table I) indicate that under conditions which cause removal of iodine, or even of bromine, from the 3 or 5 position (with reference to methyl), the 2-iodine is completely unaffected. These results are fully in accord with the original assumptions and are considered, incidentally, as a further justification for the use of stannous chloride in this and earlier work.

A quantitative comparison of the rates of removal of iodine (Table II) from 2-iodo-aniline and from 2,5-di-iodo-4-aminotoluene (only the 5-iodine is removed in the latter case) has been made and the former reaction is found to be about one-third more rapid. Fair constants for the velocity of the reaction have been calculated on the assumption that it is not influenced by changes in the concentration of stannous chloride. The latter, however, is relatively large in these cases. More decisive results on this point⁴ have been obtained in other instances.

Experimental Part

2-Iodo-4-nitrotoluene.—*o*-Toluidine was nitrated by a method⁵ recommended for the nitration of *p*-toluidine; a 70% yield of crude 2-amino-4-nitrotoluene was obtained. The 2-iodo-4-nitrotoluene was made according to Willgerodt and Kok⁶ with a 90% yield. It formed nearly white crystals; m. p., 54°.⁷

2-Iodo-4-aminotoluene.—The nitro compound was reduced with tin and hydrochloric acid and the base recovered by steam distillation; yield, 90%. The pure substance melted at 39° and its acetyl derivative at 130°.⁸

2,5-Di-iodo-4-aminotoluene.⁹—A mixture of 5 g. of 2-iodo-4-aminotoluene, 5.4 g. of iodine, 2.5 g. of calcium carbonate and 10 cc. each of water and ether was refluxed on

³ Wheeler and Liddle, *Am. Chem. J.*, **42**, 453 (1909).

⁴ To be presented later by Dr. J. R. Sampey.

⁵ Houben-Weyl, "Die Methoden der organischen Chemie," Georg Thieme, Leipzig, 1924, vol. 4, p. 139.

⁶ Willgerodt and Kok, *Ber.*, **41**, 2077 (1908).

⁷ The melting point has previously been given as 58° (Ref. 6) and 51° [Reverdin, *Ber.*, **30**, 3000 (1897)].

⁸ Willgerodt and Gartner [*Ber.*, **41**, 2813 (1908)] reduced the nitro compound with ferrous sulfate and ammonia; their base melted at 37°; acetyl derivative, m. p., 130°.

⁹ Wheeler, *Am. Chem. J.*, **44**, 501 (1910).

a water-bath for three hours and then made alkaline and subjected to steam distillation. The 2,5-di-iodo derivative came over slowly and separated for the most part in the condenser. It formed needles from alcohol; m. p., 110°.

Anal. (Carius). Calcd. for $C_7H_7NI_2$: I, 70.75. Found: 71.0, 71.2.

One g. of the substance was heated to boiling under reflux for two hours with 10% hydrochloric acid. 2-Iodo-4-aminotoluene was the chief product. Iodine equivalent to 0.3 atom was deposited in the condenser; that in the solution was not determined.

2,5-Di-iodo-4-acetotoluide.—When the base was warmed with acetic anhydride the acetyl derivative was obtained. It formed white needles; m. p., 193°.

Anal. (Carius). Calcd. for $C_9H_9ONI_2$: I, 63.34. Found: 63.37, 63.47.

2-Iodo-5-bromo-4-acetotoluide.—2-Iodo-acetotoluide was dissolved in five parts of glacial acetic acid, treated with one mole of bromine and allowed to stand for 12 hours. The yield was nearly quantitative. The purified product formed white needles; m. p., 165–166°. When treated with additional bromine under similar conditions it did not react further.

Anal. (Carius). Calcd. for C_9H_9ONBrI : AgBr + AgI, 119.4. Found: 118.6, 118.4.

2-Iodo-5-bromo-4-aminotoluene.—The acetyl derivative was refluxed for ten minutes with 20% hydrochloric acid and the base was recovered by steam distillation; m. p., 86–87°.

Anal. (Carius). Calcd. for C_7H_7NBrI : AgBr + AgI, 135.0. Found: 135.7, 135.6.

2-Iodo-3,5-dibromo-4-aminotoluene.—2-Iodo-4-aminotoluene was brominated in glacial acetic acid solution, using two moles of bromine. The use of less bromine leads to the same product, mixed with unaltered material. After steam distillation, the substance crystallized from alcohol in light brown needles; m. p., 109°; yield, 75%.

Anal. (Carius). Calcd. for $C_7H_6NBr_2I$: AgBr + AgI, 164.6. Found: 164.0.

2-Iodo-3,5-dibromo-4-acetotoluide.—As might have been expected, the base did not acetylate readily. Acetic anhydride was without action but heating with acetyl chloride readily gave the acetyl derivative. From alcohol it separated in fine, white needles; m. p., 228–229°.

Anal. (Carius). Calcd. for $C_9H_6ONBr_2I$: AgBr + AgI, 141.0. Found: 140.3, 139.7.

2,3,5-Tri-iodo-4-aminotoluene.—To a solution of 5 g. of 2-iodo-4-aminotoluene in 50 cc. of glacial acetic acid was added 7.8 g. (2 moles) of iodine monochloride, and the mixture allowed to stand for 24 hours. A tarry mass separated. Water was added and the supernatant liquid decanted. On addition of alkali and steam distillation only 2,5-di-iodo-4-aminotoluene came over. When this was removed, the residue was extracted with hot alcohol and the solution decolorized with charcoal. Repeated recrystallizations from a mixture of alcohol and chloroform gave a small yield of light brown needles, melting constantly at 120–121°.

Anal. (Carius). Calcd. for $C_7H_6NI_3$: I, 78.55. Found: 78.42, 78.23.

The base was not acetylated by hot acetic anhydride. As acetyl chloride would probably have caused liberation of iodine, no further attempt at acetylation was made.

Action of Bromine on 2,5-Di-iodo-4-aminotoluene.—The di-iodotoluidine (0.5 g.) was dissolved in 15 cc. of glacial acetic acid. To this was added 0.44 g. (2 molecular proportions) of bromine, also dissolved in acetic acid, and the whole was allowed to stand for 24 hours. Addition of an excess of alkali and steam distillation gave 0.4 g. of a product melting at 108° which, when mixed with pure 2-iodo-3,5-dibromo-4-

aminotoluene, melted at 109° . The more mobile iodine had thus been replaced by bromine while the iodine in the 2 position was unaffected.

Hydrolysis and Reduction with Hydrochloric Acid and Stannous Chloride.—As some of the halogenated toluidines described above were difficultly soluble in hot hydrochloric acid, they were dissolved in a mixture of equal volumes of concd. hydrochloric acid and glacial acetic acid. The amount of amine was so chosen that the solution was approximately 0.055 *M* in each case. An excess of stannous chloride (2 moles for each atom of halogen present) was then added and the solutions were heated under reflux to active boiling for the times indicated in Table I.

In the last column of Table I are listed the products isolated in each case. These were identified by the melting points of the free base or acetyl derivative or both. In each instance the identification was confirmed by determining the melting point of a mixture of the product with a known sample of the pure substance. Large samples were not used and the difference between the reported totals and 100% represents losses in recovery and separation, rather than side reactions. In no case was there any indication of the removal of iodine in the 2 position with formation of *p*-toluidine.

TABLE I
REACTION WITH HYDROCHLORIC ACID AND STANNOUS CHLORIDE

Substance used	Time of hydrolysis, hours	Products recovered
2-Iodo-4-aminotoluene	8.0	Unaltered material only
2,5-Di-iodo-4-aminotoluene	0.5	20% unaltered; 30% of 2-iodo-4-aminotoluene
2,3,5-Tri-iodo-4-aminotoluene	1.5	No unaltered material; 50% of 2-iodo-4-aminotoluene
	1.5	2-Iodo-4-aminotoluene only
2-Iodo-5-bromo-4-aminotoluene	8.0	5% unaltered; 70% of 2-iodo-4-aminotoluene
2-Iodo-3,5-dibromo-4-aminotoluene	4.0	50% of 2-iodo-5-bromo-4-aminotoluene
	8.0	Chiefly 2-iodo-4-aminotoluene; a little 2-iodo-5-bromo derivative.

Quantitative Comparison of the Rates of Removal of Iodine from 2,5-Di-iodo-4-aminotoluene and 2-Iodo-aniline.—To a solution of 0.00066 mole of substance in 10 cc. of glacial acetic acid was added 5 cc. of 10% hydrochloric acid containing 0.5 g. of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$. In each experiment such a mixture was heated in a rapidly boiling water-bath for the time indicated, then quickly cooled and diluted with water. An extraction with chloroform at this point removed a small amount of material which otherwise gave an interfering color in the subsequent titration. Iodine was determined^{2b} by the method of Fresenius. The atomic % of iodine removed in each case, together with the values of *K* calculated

on the assumption that the reaction is of the first order, are given in Table II.

TABLE II
RATE OF IODINE REMOVAL

Time, min.	2-Iodo-aniline		2,5-Di-iodo-4-aminotoluene ^a	
	Reaction, %	K	Reaction, %	K
5	7.82	0.0165	6.72	0.0137
15	25.18	.0194	23.13	.0169
30	49.18	.0226	36.22	.0150
60	75.19	.0232	61.46	.0161
120	93.23	.0225	83.50	.0150

^a Only one iodine is reactive.

Summary

1. A number of new halogen derivatives of 2-iodo-4-aminotoluene have been prepared.

2. A study of the selectivity and rate of halogen removal in these compounds offers striking confirmation of predictions based on a consideration of the removable halogens as positive.

POSITIVE HALOGENS ATTACHED TO CARBON IN THE AROMATIC SERIES. V. ANALOGY BETWEEN POSITIVE AND NEGATIVE HALOGENS

BY BEN H. NICOLET

RECEIVED MARCH 26, 1927

PUBLISHED JULY 5, 1927

The pronounced reactivity toward all alkaline reagents of the halogens in 2,4- and 2,6-dinitrophenyl halides is well known. The halogens are removed as halide ion and replaced by —OH, —NH₂, etc. Very few chemists have hesitated to attribute this increase in reactivity to an increase in the negative character of the halogen in question by the nitro groups, which in turn are usually conceded, in recent years at least,¹ to be positive in character. The fact that no case was known in which a halogen attached to carbon in a benzene ring was given a conspicuously negative character by substituents occupying only positions *meta* to it, appears to have caused little apprehension.

Recent papers² from this Laboratory have discussed as positive certain halogens (bromine and, more conspicuously, iodine) which, when occupying positions *ortho* or *para* to one or more amino or hydroxyl groups, were

¹ Fry, "Electronic Conception of Valence," Longmans, Green and Co., 1921, p. 122. Stieglitz, *THIS JOURNAL*, **44**, 1305 (1922). Shoesmith, Hetherington and Slater, *J. Chem. Soc.*, 125, 1314 (1924).

² (a) Nicolet, *THIS JOURNAL*, **43**, 2081 (1921). (b) Nicolet and Sampey, *ibid.*, **49**, 1796 (1927). (c) Nicolet and Ray, *ibid.*, **49**, 1801 (1927). (d) Nicolet and Sandin, *ibid.*, **49**, 1806 (1927).

hydrolyzed (usually in acid solution) in such a way that the halogen was replaced by hydrogen, while the solution acquired oxidizing properties, as shown by the liberation of halogen, the formation of more highly substituted products, or the oxidation of suitable³ reducing agents. This interpretation appears to have been less widely accepted, perhaps because of its relative novelty, although reactions seeming to justify it have been found in all the suitable cases investigated.

The present paper records an unsuccessful attempt to demonstrate positive halogen in what is perhaps the ideal case of those subject to the limitation that only *meta* substituents should be present. 3,5-Dinitroiodobenzene has been prepared, and shown to have no appreciable tendency to split off iodine when heated at 100° in acid solution.

In this connection, however, it was decided to test also the ease of hydrolysis of 3,5-diaminochlorobenzene by alkalies. This compound contains its chlorine (the most negative of the halogens, with the exception of fluorine) *meta* to two amino groups. It was boiled for two hours with an alcoholic solution of sodium ethylate, and allowed to stand two days longer, without the slightest observable liberation of chloride ion. One is thus faced with the following paradox: two amino groups, suitably located, suffice to give to iodine (or even to bromine)⁴ a pronounced positive character; two nitro groups, suitably located, give to chlorine (or even to bromine or iodine) a pronounced negative character; but neither two nitro groups, both *meta* to halogen (even iodine), nor two amino groups, both *meta* to halogen (even chlorine) suffice to give a character which is definitely positive or negative, respectively.

One conclusion appears to be that the negativity and positivity, respectively, of halogens attached to carbon in the benzene ring, rest on approximately the same basis. A further conclusion might well be that if one is to assume polarity at all (and this seems necessary, to explain the great difference in character of the two types of reaction discussed), one must further assume that the character of the reaction is such that the latter is definitely conditioned by the presence of suitable groups in the *ortho* or *para* positions. The logical interpretation of this assumption would be that the reactions in each case are due to the possibility of the formation of intermediate products of a special (presumably quinoidal) type. A possible interpretation of this sort for the reactions of compounds assumed to contain positive halogens will be given below.

Extension of the reasoning outlined leads to another consequence. For those chemists who wish to attribute polar structures (or structures at least partially polar) to organic compounds in general, it may be nec-

³ Usually stannous chloride; as to its "suitability," see Ref. 2.

⁴ But not to chlorine which, however, shows similar properties in 2,4,6-triaminobenzene.

essary to recognize as a fact that non-reactivity, under given conditions, of a certain atom or radical has no bearing whatever on the structure to be attributed; or, to state it differently, altogether aside from the polar (or partially polar) structure which a given molecule may possess, demonstration of the structure in question by a given diagnostic reaction depends also on other conditions, which may or may not permit the expected reaction to take place.

The considerations discussed above suggest most strongly that both the types of hydrolysis mentioned take place through the formation of a quinoidal intermediate. In view of the discussions given by Robinson⁵ of 1,3 addition to α,β -unsaturated amino compounds, as a case of addition to a special type of conjugated system, it seems especially tempting to assume that the elimination of halogens in the positive form from amino derivatives⁶ of the type discussed, may take place by 1,3 elimination from an analogous system in the way pictured below.

It is an experimental fact that halogen is liberated in positive form when compounds of the type indicated are heated in acid solution. It is also an experimental fact, although the data have not yet been published, that in analogous cases a quantitative study of the reaction involved when analogous compounds are heated with acid and stannous chloride has shown that the reaction rate is not proportional to the concentration of the stannous chloride. It would seem to follow that the reaction in the presence of stannous chloride (which is the one more generally studied) is really a succession of reactions of which the first is simply one of hydrolysis (or at least one independent of the presence of the reducing agent), followed by the reduction of the positive halogen as it appears in the initial reaction. The mechanism may prove, on further study, to be other than that outlined above, but it is not believed likely that the principles stated will require serious modification.

Experimental Part

3,5-Diaminochlorobenzene.—This substance has been made by Cohn,⁷ by the reduction of 3,5-dinitrochlorobenzene. A method analogous to that by which Jackson and Calvert⁸ obtained the corresponding bromo compound was preferred.

⁵ (a) Hamilton and Robinson, *J. Chem. Soc.*, **109**, 1029 (1916). (b) Robinson, *ibid.*, **109**, 1038 (1916).

⁶ The possible extension of this type of reaction to phenolic derivatives is obvious.

⁷ Cohn, *Monatsh.*, **22**, 119 (1901).

⁸ Jackson and Calvert, *Am. Chem. J.*, **18**, 487 (1896).

2,4,6-Tribromo-3,5-dinitrochlorobenzene⁹ was reduced with tin and concd. hydrochloric acid; with the addition of some glacial acetic acid to increase the solubility of the dinitro compound, the reduction was completed in two hours on the water-bath. The product was further identified by the preparation of its diacetyl and dibenzoyl derivatives.⁷

ATTEMPTED HYDROLYSIS.—Jackson and Calvert⁸ say of 3,5-diaminobromobenzene, "Sodic hydrate seems to have no action even when warmed with it several minutes on the water-bath." One g. of 3,5-diacetylaminochlorobenzene was added to a solution of 2 g. of sodium in 50 cc. of alcohol; the mixture was refluxed for two hours, and allowed to stand for two days. The solution contained only a trace of chloride ion, and a control showed an equal trace in the sodium ethylate so prepared. It was shown that the acetyl derivative was completely hydrolyzed under the conditions present; on reacylation, more than 90% of the original material was recovered as the diacetyl derivative. There was thus no evidence of hydrolysis.

3,5-Dinitro-aniline.¹⁰—Flürscheim,¹¹ reviewing the work of Bader¹² and de Kock,¹³ described a method for obtaining this substance in 62% yield. A 74% yield was obtained as follows.

Hydrogen sulfide was passed into a mixture of 100 cc. of 95% alcohol and 60 cc. of concd. ammonium hydroxide until the weight increased 5.5 g. This solution was added drop by drop to a refluxing solution of 6 g. of 1,3,5-trinitrobenzene in 150 cc. of alcohol, and heating continued for one hour after addition was complete. The mixture was then collected, filtered to remove sulfur, and the alcohol distilled off. The residue was extracted thoroughly with hot water, and the extract concentrated till crystallization began, and then cooled in ice water. The product, recrystallized from hot water, melted at 155–156°.

3,5-Dinitro-iodobenzene.—The amino group was replaced by iodine in the usual way, and the product recrystallized from 60% alcohol. It formed golden plates; m. p., 99°.

Anal. (Carius). Calcd. for $C_6H_4O_2N_2I$: I, 43.26. Found: 43.14.

ATTEMPTED HYDROLYSIS.—Dinitro-iodobenzene (0.2 g.) was dissolved in 15 cc. of acetic acid and 15 cc. of 10% sulfuric acid added, and the mixture refluxed for one hour. No iodine color appeared, and the solution gave no test for inorganic iodine. Most of the material was recovered unaltered.

3,5-Diacetylamino-iodobenzene.—The dinitro-compound was reduced with tin and hydrochloric acid, and the tin removed with hydrogen sulfide. Excess of sodium acetate was added, and then an excess of acetic anhydride. The acetyl derivative which separated melted after recrystallization at 291°.

Anal. (Carius). Calcd. for $C_{10}H_{11}O_2N_2I$: I, 39.94. Found: 40.22.

Summary

1. 2,4-Dinitrochlorobenzene and 2,4-diamino-iodobenzene are known to behave on hydrolysis as though their halogens were negative and positive, respectively. 3,5-Diaminochlorobenzene and 3,5-dinitro-iodo-

⁹ Jackson and Carlton, *Am. Chem. J.*, **31**, 375 (1904).

¹⁰ The remainder of the experimental work described was carried out by Mr. Ben Wilbur Goldman.

¹¹ Flürscheim, *J. prakt. Chem.*, [2] **71**, 537 (1905).

¹² Bader, *Ber.*, **24**, 1655 (1891).

¹³ de Kock, *Rec. trav. chim.*, **20**, 112 (1900)

benzene (both ideal cases, in terms of the theory discussed) have been prepared, and show no indications of polar characteristics for the halogens present.

2. A possible mechanism for the elimination of positive halogen from amino derivatives, involving the formation of a quinoidal intermediate compound and subsequent 1,3 elimination, has been suggested.

3. It is pointed out that failure to react under given conditions is no adequate indication of polar structure.

4. The assumption of negativity and positivity, respectively, for certain halogens attached to carbon in the benzene ring, is shown to rest on essentially the same basis.

ADDITION COMPOUNDS OF ALLYLTHIO-UREA WITH SILVER HALIDES¹

BY S. E. SHEPPARD AND H. HUDSON

RECEIVED APRIL 7, 1927

PUBLISHED JULY 5, 1927

In an investigation on photographic gelatin² it was found that the photographic activity of certain gelatins depends upon the presence of traces of mustard oil, or allyl isothiocyanate, and the thio-urea (allyl thiocarbamide, thiosinamine) derived therefrom. Further, it was shown that this photographic sensitizing power was a general property of thio-ureas and a number of cognate bodies,² being due to the formation of small traces of silver sulfide in the silver halide grains. These traces of silver sulfide were considered to constitute the so-called "sensitivity centers" of photographic theory.

The chemical reactions in this sensitizing process are essentially

In Reaction 2 sufficient alkalinity is necessary to neutralize the hydrobromic acid and the cyanamide.

The present investigation is concerned with the formation and properties of the intermediate double compounds of silver halide and thio-

¹ Read in part at the Regional Meeting of the American Chemical Society, January, 1926.

² Sheppard, *Phot. J.*, **65**, 380 (1925).

urea, indicated in Reaction 1. So far not very much information has been found in the literature concerning such compounds. Reynolds³ described a definite crystalline compound of silver bromide with thio-urea, $(\text{CSN}_2\text{H}_4)_2 \cdot \text{AgBr}$, obtained by the interaction of silver nitrate with $(\text{CSN}_2\text{H}_5)_4\text{NBr}$ in equimolecular proportions. He further stated that analogous compounds had been obtained with other silver salts, and later described these.⁴ With silver nitrate, the general result was the identification of the compounds $(\text{CSN}_2\text{H}_4)_3 \cdot \text{AgNO}_3$ and $(\text{CSN}_2\text{H}_4) \cdot \text{AgNO}_3$, while some evidence of the existence of the intermediate substance, $(\text{CSN}_2\text{H}_4)_2 \cdot \text{AgNO}_3$, was obtained.

Coming to the silver halides, he found that *silver bromide* forms two compounds with thio-urea, $(\text{CSN}_2\text{H}_4)_2 \cdot \text{AgBr}$ and $\text{CSN}_2\text{H}_4 \cdot \text{AgBr}$. With *silver chloride* he obtained only the 2:1 compound, with no evidence for the 1:1 compound, and with *silver iodide* only the 1:1 compound. It may be noted that while Reynolds obtained only a 2:1 compound with silver cyanide, and states that "as with silver chloride, a 1:1 compound has not been obtained," Rosenheim and Loewenstamm⁵ obtained by digestion of freshly precipitated silver cyanide in aqueous thio-urea white, glistening scales of a 1:1 compound, which they describe as "extraordinarily unstable, separating silver sulfide again on recrystallization."

When we turn to the substituted thio-ureas, the previous indications are much more meager. We have not yet had access to a dissertation by Falke⁶ which contains some previous work on compounds of the metal salts with thiosinamine (allyl thiocarbamide). In this a 1:1 compound with silver chloride is mentioned, occurring in "white, feathery needles."

Silver Chloride and Thiosinamine.—The compound was prepared by mixing equimolecular quantities of allyl thiocarbamide, potassium chloride and silver nitrate, each at 0.1 *M* concentration. A microcrystalline precipitate is at once formed which was filtered off and washed free from soluble salts. Analysis of this gave sulfur and silver chloride corresponding to the 1:1 compound, $\text{NH}_2 \cdot \text{C}(-\text{S})\text{NHC}_3\text{H}_5 \cdot \text{AgCl}$. Solubility measurements were made on this by percolating the powder with

distilled water at various temperatures, until saturation values were reached on analysis of the supernatant liquid.

Silver Bromide and Thiosinamine.—For the preparation of the 1:1 compound, a quantity of well-washed silver bromide was fused in a porcelain crucible. Two glass rods were allowed to freeze in the melt, and served as supports after the crucible was broken away. The fused mass was cleaned by immersion in sodium thiosulfate solution and water, and then suspended in an aqueous solution of allyl thiocarbamide (thiosinamine), one part in 1000 parts of water. Bunches of small, needle-shaped crystals developed on the surface of the silver bromide overnight (Fig. 1). A quantity of crystals were grown in this manner, washed with distilled water and dried over sulfuric acid. Analysis was made of the silver content by digestion with ammonium sulfide, the silver sulfide formed being filtered off, dried and weighed. A sample analysis follows.

Fig. 1 Crystals of allyl thiocarbamide—silver bromide. Magnification eight times.

Anal. Subs., 0.1534 Ag_2S calcd. for $\text{AgBr} \cdot \text{C}_4\text{N}_2\text{H}_5\text{S}$, 0.0626. Ag : calcd., 35.50. Found: 35.51.

Control analyses of the nitrogen by Kjeldahl's method confirmed this, corresponding to 97.4% of that calculated for $\text{AgBr} \cdot \text{C}_4\text{N}_2\text{H}_5\text{S}$. This compound corresponds, therefore, to the 1:1 compound of silver bromide and thio-urea, described by Reynolds, and the 1:1 compound of silver chloride and thiosinamine, ascribed to Falke.

Solubility measurements were made on the 1:1 silver bromide compound at 15, 25, 35 and 50°. A quantity of the compound was put in known volumes of water and shaken for 48 hours in a thermostat kept constant to 0.1°, and the amount dissolved determined by conversion to silver sulfide. The values obtained are given in Table II.

Silver Iodide and Thiosinamine.—Although there was evidently an action of dilute thiosinamine solution upon fused silver iodide, it was

not found possible to grow crystals in the same way as with silver bromide. An attempt to prepare the 1:1 compound was made as follows.

Eleven and six-tenths g. of allyl thiocarbamide and 16.6 g. of potassium iodide were dissolved in 500 cc. of water. To this there was slowly added with stirring 17.0 g. of silver nitrate in water. A voluminous precipitate formed which settled to the bottom, consolidating to a sticky, plastic mass. The supernatant liquor gave no reaction for silver sulfide when heated with ammonia. From this it appears that the 1:1 compound is formed, and that its solubility at room temperature is of the order of silver iodide or silver sulfide.

The solid decomposes very readily, giving silver sulfide, so that it appears that the following reaction had gone to completion: $\text{AgNO}_3 + \text{C}_4\text{N}_2\text{H}_8\text{S} + \text{KI} = \text{AgI} \cdot \text{C}_4\text{N}_2\text{H}_8\text{S} + \text{KNO}_3$. The compound was difficult to isolate in a pure state because it formed a glassy mass instead of crystallizing. It appears, however, somewhat soluble in alcohol from which it may be precipitated in a semi-colloidal state by the addition of water.

Fig. 2.—Solubility of silver halide-allyl thiocarbamide compound in water. \circ , silver chloride; \times , silver bromide; \triangle , silver iodide.

A solubility determination was made at 50° with the result given in Table III.

Effect of Soluble Halides.—Preliminary measurements have shown that excess of the soluble halides reduces the solubility of the double compounds in water. This effect is being studied, as well as the influence of excess of soluble halides and other salts on the formation of the double compounds and on their decomposition.

Composition and Constitution.—On comparing our observations with those of previous observers, we may note that although in several of our experiments considerable excess of allyl thiocarbamide was used over the 1:1 molecular ratio of silver halide:allyl thiocarbamide, and up to 1 mole of silver halide to 2 moles of allyl thiocarbamide, no evidence of other double compounds, for example, $1\text{Ag Br} : 2\text{C}_4\text{H}_8\text{N}_2\text{S}$, was obtained, but only of solutions. It is possible, therefore, that the 1:2 compound of allyl thiocarbamide is more difficult to isolate than that of thiocarbamide itself, and this is being investigated.

The compounds of thio-ureas with metal salts have been considered from the point of view of the Werner coordination theory by Rosenheim and Loewenstamm.⁵ The mode of combination of the silver halide will depend upon the constitution assigned to the thio-ureas. Lecher and co-workers⁷ in an important memoir on the "Constitution of Thiourea and the Thiourea Salts" give strong evidence for the ampholytic character of thio-urea, according to the following general scheme.

On this conception, the 1:1 double compounds would have the constitution

The contiguity of the silver ion and the negative sulfur atom agrees with the ready formation of silver sulfide.

Relation to Photographic Sensitizing.—The isolation and observed solubilities of these double compounds have important bearings on photographic sensitization, which will be discussed elsewhere. It may be suggested, however, that the much lower solubility of the silver iodide compound, compared with that of the 1:1 silver bromide compound, make it an important intermediate in the process.

It is known not only that silver iodide in small amounts (less than 3%) considerably influences photographic sensitivity, but also that in certain

⁷ Lecher and co-workers, *Ann.*, **445**, 35 (1925).

high-speed emulsions the proportion of iodide is greater in the larger than in the smaller grains.⁸ Further, it has been shown by Sheppard, Wightman and Trivelli⁹ and by Clark¹⁰ that the larger grains resist desensitizing more than the small ones. This may be due to the silver sulfide nuclei being larger or more firmly "rooted," and protected by silver iodide rather than silver bromide, in the larger grains.

Summary

1. The literature on the double compounds of thio-ureas with silver salts is briefly reviewed.
2. The preparation of the 1:1 compounds of allylthio-urea with silver chloride, silver bromide and silver iodide is described.
3. Solubility measurements are given for the temperature range 15 to 50°.
4. The constitution of these double compounds is discussed and their relation of photographic sensitizing.

PHOTOSYNTHESIS WITH MALACHITE GREEN

BY DEAN BURK

RECEIVED APRIL 11, 1927

PUBLISHED JULY 5, 1927

According to Baly, Heilbron and Barker¹ and Baly,² "an aqueous solution of malachite green saturated with carbon dioxide yields formaldehyde on exposure to light behind a thick plate glass screen. In the absence of carbon dioxide no formaldehyde is produced." No details of technique in support of this claim were offered. Baur and Büchi³ repeated the experiment, but they were unable to conclude that the formaldehyde came from the carbon dioxide. Indeed there was no doubt, from their experiments, that the presence of carbon dioxide in the exposed solutions of malachite green, the concentrations of which varied eight-fold, from 15 to 125 parts per million, reduced the yield of formaldehyde. When the absence of all carbonate or bicarbonate ions was insured by the addition of varying amounts of barium hydroxide, the yields of formaldehyde were increased decidedly, even though the solutions may have been partially or entirely discolored before exposure was made, owing to the alkalinity. The fact that the colorless solutions, when

exposed, gave relatively large amounts of formaldehyde, combined with the fact that the yield was reduced when the insolation was made behind glass walls of increasing thickness, strongly supported the view that only the colorless ultraviolet rays were responsible for the photochemical effect, and still further weakened the original conception of Baly, Heilbron and Barker that carbon dioxide could be reduced by *visible* light when a photochemical catalyst like malachite green, which may combine with it, is present also. Baly has since reversed his position, and has stated⁴ that formaldehyde may form even in the absence of carbon dioxide. The present paper will offer evidence, obtained by experimental methods different from those previously used, which extends the general findings of these investigators.

Experimental Part

The new experimental feature of the technique was the use of condensed sunlight. The lenses were large, spherical, colorless, common glass flasks 30 cm. in diameter filled with clear water and mounted on stationary iron tripods. Calculations indicated that the intensity of sunlight which had passed through them was increased to a maximum of approximately 5000-fold; for noon sunlight this intensity would be about five million times that of an ordinary 40-watt Mazda lamp. Exposure behind one of these lenses on a clear day was considered to be equal, as regards the amount or total energy value of the light, to exposure to ordinary sunlight for about a month of clear days. (This assumption was confirmed experimentally by study of other relatively uncomplicated reactions, such as the reduction of Fehling's or Benedict's solutions, the decomposition of uranyl formate, etc., where justifiable interpretation was allowable because the rates of reaction were rapid enough and the equilibrium points far enough on the sides of the resultants.) The beam of light was generally 6 mm. in diameter at the point where it entered the exposed solution. The temperature of the solution was kept below 30° by immersion of the containing vessel a little below the surface of a simple water-bath. The solutions, whose concentrations in these experiments were always 50 parts per million (0.005%) of malachite green chloride, were exposed in glass bulbs blown on the end of common soft glass tubes about 30 cm. in length and 12 mm. in diameter. The bulbs were quite spherical, had a capacity of from 15 to 50 cc., were just as thin as safety would allow (from 0.05 to 0.1 mm.), and were very transparent. The tubes were cleaned with chromic acid at 100°, hot alcoholic potassium hydroxide, hot concd. nitric acid, and many rinsings of distilled water. (In order to allow for the movement of the sun, the positions of the bulbs were changed every 20 minutes. No heliostat was employed.) The tubes were exposed to lenses for four to six hours a day, but they also

⁴ Baly, *Ind. Eng. Chem.*, **16**, 1016 (1924).

received the ordinary sunlight during the remaining hours. A control tube containing a solution of similar composition, but protected from light by being heavily wrapped in tin foil, was placed beside each exposed tube, in the same thermostat. Since the two corresponding tubes were treated as exactly alike as possible (except that their volumes frequently differed), except for exposure, any difference found between their contents upon examination could be considered as having been caused by either primary or secondary effects of light. The unexposed tubes were numbered "a." The sealed tubes were first evacuated with a water pump. The unsealed tubes were protected by hoods of tin foil bent over in such a manner as to allow entrance of air but to exclude foreign matter. The water used to make up the solutions was twice distilled and had a conductivity not greater than 5×10^{-6} mhos.

The ammonium carbonate used was Baker's $(\text{NH}_4)_2\text{CO}_3 \cdot \text{NH}_4\text{CO}_2\text{NH}_2$, mol. wt. 174.15; 0.18 cc. of the 35.0 *N* sulfuric acid used in Expts. 9 and 10 was required to neutralize 0.500 g. of it to full methyl orange. The acid was contained in a side arm sealed into the neck of the tube, and was not mixed with the rest of the contents until after vacuum sealing. Ammonium carbonate was used since, if formaldehyde and oxygen gas were the photochemical end-products of the reaction to be studied, the ammonia could possibly assist in removing both of them, by forming hexamethylenetetramine (and other bases) as well as nitrites and nitrates.

Expts. 1-6 and 11-12 were exposed to lenses for 19 hours during December 27 to 30. Expts. 7-10 were exposed to lenses for 25 hours during December 15 to 23.

Results and Discussion

Table I contains the results of the experiments selected for mention.

The magnitudes of the concentrations of formaldehyde found agree exactly with those observed by Baur and Büchi.³ In acid solutions there was never more than 1 p.p.m. (part per million), generally much less; in the most alkaline solutions, 4 to 6 p.p.m. The Schryver test as employed by the writer was sensitive to 0.1 p.p.m., the Gallic acid test to exactly 1 p.p.m. This explains why in solutions where 1 p.p.m. or less was found by Schryver's, the Gallic test was negative. The standard solutions for comparison were made up in the presence as well as the absence of malachite green. At 1 p.p.m. of formaldehyde neither test is affected (within 10%) by the presence of 50 p.p.m. of malachite green, since the strong acidity of both sets of reagents instantly destroys the color of the dye. Baur and Büchi's statement that the presence of air makes little difference in the amount of formaldehyde formed is confirmed. Under the experimental conditions employed it would require a statistical study of many repeated experiments to show a real difference. The fact that the Gallic test, which is a good hydrolyzing agent on account

of the practically pure sulfuric acid which it contains, never indicates a greater concentration than does the Schryver test is good inferential evidence that little or none of the formaldehyde is being removed by the formation of condensation compounds with malachite green or any of its photochemical decomposition products, such as amines. This might be expected, perhaps, since at this dilution the free energies of such reactions would be unfavorable to condensation. These experiments make it plain why Baur and Büchi found that carbon dioxide decreased the concentration of formaldehyde observed and that barium hydroxide

increased it; the amount is controlled by either the primary or secondary effects of the hydroxyl-ion concentration. The production of these small amounts of formaldehyde from malachite green was found by the writer to be practically independent, within ranges of 100-fold or more, of the intensity of the sunlight and the length of exposure (and the concentration of malachite green). Therefore, if solutions of from about 25 to 250 p.p.m. of malachite green were exposed to sunlight in the presence of carbonic acid (etc.) at a P_H less than 10, the finding of perhaps five or more p.p.m. of formaldehyde would be, contrary to current opinion and the opinion of the investigators cited,³ quite significant in relation to carbon dioxide reduction. In acid solutions, as little as 1 p.p.m. would be significant. This view is supported by the fact that while the maximum concentration of formaldehyde which could form from a solution of 50 p.p.m. of malachite green, on the basis of all its carbon molecules, is 44 p.p.m. (88.2%), nevertheless, if the benzene ring carbon molecules are not considered, but only the four methyl radicals, the maximum concentration would be only seven p.p.m. (15.1%). While it is probable that the significant amounts suggested above have not been found by any workers, it must be remembered that the experimental conditions have been quite simple, and others might be devised where the desired result would be obtained. It is conceivable that conditions could be obtained where the amount of formaldehyde formed from the dye would be entirely unqualifying, that is to say, a concentration less than 0.1 p.p.m.

The potassium permanganate titration values indicate no significant change as regards the formation of reducing substances such as hydroxylamine and formic acid, since each exposed solution had the same value as its corresponding unexposed one.

The Nessler tests show that bases, presumably amines, are formed upon exposure. The amount of photochemical nitrogen decomposition as amines was greater by several times than the amount of carbon decomposition as formaldehyde. The amounts of amines found are smaller in acid solutions. The reaction is shown to be entirely photochemical.

The values for P_H are accurate to 0.4, since the color of the dye interfered somewhat.

Expts. 7 to 10 show that the presence of ammonium, carbonate or bicarbonate ions, or of carbonic acid, have in no way affected the amount of formaldehyde formed, the P_H being taken into consideration.

The following results could not be placed conveniently in the table.

Griess, Trommsdorff and diphenylamine tests were negative in all cases except Expts. 2 and 7, where the presence of 1 p.p.m. of nitrite was indicated, showing that for the oxidation of the ammonia or other decomposition products of malachite green, conditions of exposure to sunlight, aeration and alkalinity are necessary. The Griess and Tromms-

dorff tests were sensitive to 0.1 p.p.m., the diphenylamine to about 1 p.p.m. At 1 p.p.m. of nitrite, smaller amounts of nitrate also present could not be distinguished. The usual method of reducing the nitrate with zinc and testing for increase of nitrite by the Griess test, which is specific, would not suffice. The amount of nitrite formed is not dependent on the ammonium-ion concentration, since Expt. 7 contained much more of the latter than did Expt. 2. The role of air is not known, but simple absorption of atmospheric oxygen-nitrogen compounds is precluded by experiments not reported in which many unexposed, unsealed tubes were found never to contain nitrites. While ammonia may be oxidized to nitrates and nitrites by short-wave ultraviolet light⁵ (200m μ), the oxidation of ammonia or ammonia-like forms, amines, etc., in the presence of sunlight-absorbing compounds, is not without example, as will be indicated in a later publication. The writer has found that ferric chloride, zinc oxide and mercuric oxide can oxidize ammonia to nitrites or nitrates in the presence of sunlight.

No odor was detected in any tubes, except that of ammonia in Expts. 7, 7a, 8 and 8a.

Reduction of Fehling's solution and the Molisch carbohydrate test were negative in all cases except, of course, in Expts. 11, 11a, 12 and 12a, where they were all of equal magnitude. No red ring was observed in the Molisch test, but rather the typical white cloud, insoluble in concd. sulfuric acid, given by formaldehyde.

All of the solutions except 2 and 2a gave the same slight black precipitate with iodine in potassium iodide solution (12.5 g. of iodine in a solution of 16.5 g. of potassium iodide in 100 cc. of water). When formaldehyde was added before the reagent (Thatcher test), all of the solutions gave the same kind and amount of precipitate except 2, 2a, 5, 5a, which gave smaller precipitates, and 11, 11a, 12, 12a, which gave also C₆H₁₂-N₄I₄, hexamethylenetetraminetetra-iodide.

The writer wishes to express his appreciation of assistance and advice offered by Professor Dennis R. Hoagland.

Summary

1. While previous observations have indicated that malachite green decomposes in sunlight to yield formaldehyde, the present experiments show that amines are produced also, and in greater concentration than formaldehyde. When the conditions are aerobic and alkaline, nitrites are produced also.

2. The interpretation of photosynthetic experiments with malachite green solutions is prejudiced little if any by the formation of formaldehyde

⁵ Berthelot and Gaudechon, *Compt. rend.*, **152**, 522 (1911). Baly, Heilbron and Stern, *J. Chem. Soc.*, **123**, 185 (1923).

from the dye itself, since the order of magnitude of the concentration of formaldehyde is extremely small, without exception, and can be controlled at will by varying the experimental conditions, particularly of hydrogen-ion concentration.

THE REACTION BETWEEN CINNAMYL CHLORIDE, MAGNESIUM AND CARBON DIOXIDE

BY HENRY GILMAN AND STANTON A. HARRIS

RECEIVED APRIL 16, 1927

PUBLISHED JULY 5, 1927

Introduction

In several quantitative studies, it has been proved that a few typical organomagnesium halides do not add to a wide variety of ethylenic and acetylenic hydrocarbons. Gilman and Crawford¹ used ethylmagnesium iodide with 11 ethylenic hydrocarbons; Gilman and Shumaker² used ethylmagnesium bromide and iodide with four acetylenic compounds; and Gilman and Peterson³ used ethylmagnesium bromide, phenylmagnesium bromide, butoxymagnesium iodide, *p*-tolylmercaptomagnesium iodide, methylaniline-magnesium bromide and ethylzinc iodide with 18 variously substituted ethylenic compounds.

A recent book⁴ and review⁵ of the chemistry of organomagnesium halides direct attention to the work of Rupe and Bürgin⁶ who have presumably proved that cinnamylmagnesium chloride (and bromide) adds to the ethylenic linkage of the cinnamyl group. They postulate the following reactions.

In support of the hydrocarbon (1,4-diphenyl-hexene-1) obtained by the addition of one molecule of cinnamylmagnesium chloride to the ethylenic linkage of another like molecule, they obtained phenylsuccinic and benzoic acids among the products of oxidation of their hydrocarbon. They were unsuccessful in their attempts to effect a reaction between the cinnamylmagnesium chloride (or bromide) and aldehydes or ketones.

The hydrocarbon which they obtained in limited amounts after eight

fractional distillations has not as yet been identified by us. However, their mechanism of reaction is probably incorrect. A Grignard reagent is formed when cinnamyl chloride reacts with magnesium in ether. This RMgX compound is not the cinnamylmagnesium chloride which they postulate in the explanation of the ethylenic hydrocarbon. Instead, it is an RMgX compound formed by the rearrangement of the cinnamylmagnesium chloride.

Evidence for the correctness of the RMgX compound formed by rearrangement is the production of methyl atropic acid, $\text{C}_6\text{H}_5\text{C}(=\text{CHCH}_3)\text{-COOH}$, when cinnamyl chloride and carbon dioxide are added to magnesium under ether.

Rearrangements of this type have previously been noted by others with related Grignard reagents. For example, benzylmagnesium chloride⁷ with formaldehyde gives *o*-tolylcarbinol and not β -phenylethyl alcohol. Here we have a comparable rearrangement, where the -MgCl group may be assumed to have gone from an alpha to a gamma carbon atom.

So far as known, carbon dioxide has not given such rearrangement reactions with benzylmagnesium chloride and triphenylmethylmagnesium chloride. The reagents that generally induce such rearrangement are formaldehyde and benzaldehyde. Some unpublished work with J. E. Kirby on the mechanism of these rearrangements shows that ethyl chlorocarbonate gives the *ortho* product of rearrangement with benzylmagnesium chloride (namely, ethyl *o*-toluate), and that α -naphthylmethylmagnesium chloride gives abnormal products with both formaldehyde and ethyl chlorocarbonate.

Experimental Part

The cinnamyl chloride was prepared in 78% yield according to Rupe and Bürgin.⁶ It was used in preference to the bromide, because such chlorides give a higher yield of RMgX compound than do the corresponding bromides.⁸ One-half of the magnesium they used was activated

⁷ Schmidlin and Garcia-Banús, *Ber.*, 45, 3193 (1912). In this article mention is also made of the rearrangement of triphenylmethylmagnesium chloride. References are given to the earlier work on both benzylmagnesium chloride and triphenylmethylmagnesium chloride.

⁸ Gilman and McCracken, *THIS JOURNAL*, 45, 2462 (1923). Gilman and Kirby, *ibid.*, 48, 1733 (1926).

according to the method of Baeyer.⁹ In our first experiments, the reaction was started with a very small amount of the highly active magnesium-copper alloy of Gilman, Peterson and Schulze.¹⁰ Later, however, it was found that the reaction started comparatively easily by the usual addition of a crystal of iodine, accompanied by moderate heating.

When allowed to proceed at room temperature, the reaction is quite vigorous and a positive color test for Grignard reagent was obtained by the use of Michler's ketone as described by Gilman and Schulze.¹¹ However, when the reaction mixture is heated prior to removing the small sample for a color test, no Grignard reagent is present. Accordingly, in subsequent runs, the reaction mixture was cooled moderately, and a stream of carbon dioxide was bubbled through the ether simultaneously with the addition of cinnamyl chloride. Because the reaction slowed down too decidedly when the cooling was effected by an ice-water bath, the cooling medium selected was running tap water.

Under these conditions, 3.7 g. or an 11.4% yield of an acid melting at 135–136° was obtained from 30.5 g. or 0.2 mole of cinnamyl chloride. In another 0.2-mole run the volume of ether was increased from 100 cc. to 500 cc., the reaction having been started with several cc. of cinnamyl chloride in 50 cc. of ether before bubbling in carbon dioxide at about 20°. The yield of acid from this run was 8.8 g., or 27.1%.

In this second run the acid was obtained as an oil. Believing that it might be a labile form of phenyl isocrotonic acid, $C_6H_5CH=CHCH_2COOH$ (the normal reaction product if the $RMgX$ compound was truly the cinnamylmagnesium chloride postulated by Rupe and Bürgin), part of it was boiled gently in a test-tube to get α -naphthol. On cooling, a solid acid was obtained identical (by mixed melting point) with that described above; m. p., 135–136°. This acid was identified as methyl atropic acid by a mixed-melting-point determination with an authentic specimen prepared according to directions of Ogialoro¹² from sodium phenylacetate, paraldehyde and acetic anhydride. Its neutralization equivalent was 161 (calcd., 162). The oil may be a stereoisomer of the 135–136° solid.

In another run, the Grignard reagent was started with iodine and

⁹ Baeyer, *Ber.*, **38**, 2759 (1905).

¹⁰ A preliminary account of this and other means of activation was given in a paper presented at the Philadelphia meeting of the American Chemical Society, September 7, 1926. Mention of the alloy is contained in a recent paper by Hurd and Webb, *This Journal*, **49**, 546 (1927).

Bars or ingots of the 12.75% copper-magnesium alloy may be purchased from the American Magnesium Corporation at Niagara Falls, New York. The powdered alloy of 200 mesh is sold by the Eastman Kodak Co., Rochester, New York.

¹¹ Gilman and Schulze, *ibid.*, **47**, 2002 (1925).

¹² Ogialoro, *Gazz. chim. ital.*, **15**, 514 (1885). Rupe, *Ann.*, **369**, 322 (1909).

moderate warming in the presence of a carbon dioxide atmosphere. The reaction was allowed to proceed at the boiling point of ether (due to the heat of reaction) and from a 0.2-mole run there was obtained 6.5 g., or a 20% yield of methyl atropic acid. There is then a restricted optimal temperature range, below which the reaction is virtually stopped, and above which the yield of acid drops.

Summary

Methyl atropic acid is obtained when cinnamyl chloride and carbon dioxide are added to magnesium in ether. The formation of this acid probably is due to the rearrangement of cinnamylmagnesium chloride.

SOME BROMINE DERIVATIVES OF PENTANOIC AND HEXANOIC ACIDS

BY R. MERCHANT, J. N. WICKERT AND C. S. MARVEL

RECEIVED APRIL 16 1927

PUBLISHED JULY 5, 1927

The ω -halogen derivatives of pentanoic and hexanoic acids are of some interest in connection with the preparation of compounds related to ornithine and lysine. Several methods of synthesis are already available but they are not entirely satisfactory in all details.

5-Bromopentanoic acid has been prepared by Cloves¹ by heating 5-phenoxy-pentanoic acid with concd. hydrobromic acid in a sealed tube at 145°. The 5-phenoxy-pentanoic acid is best prepared by Gabriel's method² from diethyl phenoxypropylmalonate. This ester has been described in several papers^{2,3} and the yields are said to be about 55% when γ -chloropropylphenyl ether is condensed with the sodium derivative of malonic ester.

All of these reactions have been reinvestigated and the methods and yields have been improved. Thus, in the preparation of diethyl phenoxypropylmalonate, the use of γ -bromopropylphenyl ether in place of the chloro compound has increased the yield of the ester to about 70–80%. The 5-phenoxy-pentanoic acid has been reacted with 48% hydrobromic acid without the use of sealed tubes to give better than 60% of the calculated amount of 5-bromopentanoic acid. A more direct preparation of this bromo acid was developed, in which the diethyl phenoxypropylmalonate was treated directly with 48% hydrobromic acid. The yield based on the ester is 65–69%.

² Gabriel, *Ber.*, **25**, 418 (1892).

³ (a) Funk, *Ber.*, **26**, 2569 (1893). (b) Granger, *Ber.*, **28**, 1199 (1895). (c) Günther, *Ber.*, **31**, 2136 (1898).

2,5-Dibromopentanoic acid has been prepared previously from diethyl α,δ -dibromopropylmalonate by hydrolysis with concd. hydrobromic acid.⁴ It has been found that the bromination of 5-bromopentanoic acid in the presence of a small amount of phosphorus tribromide⁵ proceeds smoothly to give the 2,5-dibromo acid. An attempt was made to obtain this acid by first brominating phenoxypropylmalonic acid and then removing carbon dioxide and splitting the ether acid with hydrobromic acid. This method was not at all satisfactory. Apparently, bromine enters the benzene ring and the resulting mixture of products is very hard to purify. Practically no pure 2,5-dibromopentanoic acid could be isolated from this reaction.

In a previous paper⁶ from this Laboratory a solid compound thought to be 2,6-dibromohexanoic acid was described. It was prepared by the bromination of phenoxybutylmalonic acid, followed by the elimination of carbon dioxide and the splitting of the ether with hydrobromic acid. The compound was so different in its physical properties from those of the 2,5-dibromopentanoic acid prepared in this work that it was thought advisable to prepare a sample of 2,6-dibromohexanoic acid by the bromination of 6-bromohexanoic acid. This was done and the pure 2,6-dibromo acid was obtained as a heavy liquid. The compound previously described is undoubtedly not a simple hexanoic acid derivative.

The acid chlorides and ethyl esters of 5-bromopentanoic acid and of 2,5-dibromopentanoic acid have been prepared and are described in the Experimental Part.

Experimental Part

Diethyl Phenoxypropylmalonate.—The usual procedure for the alkylation of malonic ester was followed.⁷ The quantities used were 2.5 liters of absolute alcohol, 69 g. of sodium, 720 g. of diethyl malonate and 645 g. of γ -bromopropylphenyl ether. The product was collected at 185–189° (4 mm.). The yield varied from 615 to 710 g., or 70–80%. The product did not solidify at ordinary temperatures. Its purity was shown by the saponification number 148.6, whereas the calculated value is 147; d_{20}^{25} , 1.0858; n_D^{25} , 1.488; M_D calcd., 77.45; found, 78.00.

5-Phenoxypentanoic Acid.—This product was prepared by Gabriel's² method in yields of 87–93%, based on the ester. It boiled at 175° (4 mm.) and melted at 65–66°.

5-Bromopentanoic Acid from 5-Phenoxypentanoic Acid.—A 1-liter flask was fitted

⁴ (a) Willstätter and Ettlinger, *Ann.*, **326**, 101 (1903). (b) Fischer and Suzuki, *Ber.*, **37**, 2843 (1904).

⁵ Compare the method of Clarke and Taylor for α -bromocaproic acid, "Organic Syntheses," John Wiley and Sons, New York, 1925, vol. 4, p. 9.

⁶ Marvel, MacCorquodale, Kendall and Lazier, *This Journal*, **46**, 2842 (1924).

⁷ Ref. 5, p. 11.

by means of a ground-glass connection to a 1-meter fractionating tube leading to a condenser set for distillation. In this flask were placed 330 g. of 5-phenoxy-pentanoic acid and 500 cc. of 48% hydrobromic acid. The mixture was boiled over a flame at such a rate that the temperature at the head of the fractionating column was maintained at 115–120°, thus allowing water and phenol to distil out of the reaction mixture. The reaction was complete in five to eight hours, as no more phenol distilled. The reaction mixture was diluted with about 500 cc. of water and the 5-bromopentanoic acid was collected in ether. The ether extract was separated and evaporated and the residue was distilled under reduced pressure. The yield of acid boiling at 123–131°, at 6 mm., was 195–200 g., or 63–64%. On cooling, the product solidified; m. p., 38–39°.

5-Bromopentanoic Acid from Diethyl Phenoxypropylmalonate.—In the same way, 455 g. of diethyl phenoxypropylmalonate was treated with 300 cc. of 48% hydrobromic acid. The ester hydrolyzed and the ethyl alcohol was largely converted to ethyl bromide. Large quantities of carbon dioxide were evolved so that considerable foaming occurred in the early part of the reaction. When most of the ethyl bromide had distilled, another lot of 400 cc. of hydrobromic acid was added to the reaction mixture and the heating was then continued. When no more phenol distilled, the product was isolated as described before. The yield of pure acid, b. p. 142–145°, at 13 mm., was 182–193 g., or 65–69%; m. p., 38–39°.

Ethyl 5-Bromopentanoate.—Cloves¹ has esterified 5-bromopentanoic acid with ethyl alcohol, using dry hydrogen chloride as a catalyst. He collected and analyzed a fraction boiling at 120–176°, at 15 mm. No other physical properties were recorded.

A mixture of 50 g. of the bromo acid, 300 cc. of absolute alcohol and 5 g. of concd. sulfuric acid was refluxed for about two hours. The excess of alcohol was then distilled, the remaining crude ester dissolved in ether, washed with sodium carbonate solution and distilled. The yield of ester, b. p. 94–97°, at 7 mm., was 34–42 g., or 58–72%; d_4^{24} , 1.3191; n_D^{24} , 1.4580; M_D , calcd., 43.85; found, 43.23.

5-Bromopentanoyl Chloride.—A mixture of 50 g. of 5-bromopentanoic acid and 90 g. of thionyl chloride was refluxed for about two hours and then distilled. The yield of pure acid chloride, b. p. 102–104°, at 15 mm., was 45 g., or 80%; d_4^{27} , 1.5010; n_D^{26} , 1.4879; M_D , calcd., 37.93; found, 38.29.

Anal. Subs., 0.1192, 0.4283: 6.80, 24.65 cc. of 0.1737 *N* AgNO₃. Calcd. equivalents of halogen: 0.001196, 0.004284. Found. 0.001180, 0.004265.

When treated with 30 g. of absolute alcohol, the above acid chloride gave 42 g. of the ethyl ester; b. p., 106–110°, at 20 mm.; yield, 89%.

2,5-Dibromopentanoic Acid.—A mixture of 53 g. of 5-bromopentanoic acid and 0.5 cc. of phosphorus tribromide was placed in a flask fitted to a reflux condenser by means of a ground-glass joint. Through the condenser, 60 g. of dry bromine was added. Some hydrogen bromide was evolved at room temperature. The flask was placed in an oil-bath at 70–80° for about 15 hours and finally heated for a few minutes at 110° to drive out most of the dissolved hydrogen bromide. The material was then transferred to a Claisen flask and distilled under reduced pressure. The yield of dibromo acid, b. p. 150–152°, at 5 mm., was 69 g., or 91%. The boiling point given in the literature^{4b} is 171–174°, at 13–15 mm. The neutral equivalent for the acid prepared above was found to be 261; calcd., 260; d_4^{25} , 1.8629; n_D^{25} , 1.5347; M_D , calcd., 42.47; found, 43.42.

2,5-Dibromopentanoyl Chloride.—In a flask fitted to a reflux condenser by means of a ground-glass joint was placed 150 g. of 5-bromopentanoyl chloride. Through the condenser 160 g. of dry bromine was added, over a period of two hours. The mixture was heated overnight on a steam-bath and then distilled under reduced pressure. Some

unchanged 5-bromopentanoyl chloride distilled first and then the dibromo acid chloride was collected at 138–145°, at 15 mm.; yield, 162 g., or 77%. The boiling point reported here is somewhat higher than that given by Fischer and Suzuki.^{4b}

Ethyl 2,5-Dibromopentanoate.—A mixture of 430 g. of 5-bromopentanoic acid and 275 g. of thionyl chloride was allowed to react and the excess of thionyl chloride was then distilled. The residue was brominated with 420 g. of dry bromine. The crude 2,5-dibromopentanoyl chloride thus obtained was treated with 350 cc. of absolute ethyl alcohol. The ester was distilled under reduced pressure. The yield of ester, b. p. 128–135°, at 14 mm., was 400 g., or 58%. On redistillation most of the product boiled at 133–135°, at 14 mm.; d_4^{25} , 1.6289; n_D^{25} , 1.4947, M_D , calcd., 50.51. Found. 51.53.

Anal. Subs., 0.4516, 0.4182: 18.00, 16.77 cc. of 0.1737 *N* AgNO₃. Calcd. for C₇H₁₂Br₂O₂: Br, 55.6. Found: 55.4, 55.4.

6-Bromohexanoic Acid.—A mixture of 153 g. of diethyl phenoxybutylmalonate and 500 cc. of 48% hydrobromic acid was treated as described for the preparation of 5-bromopentanoic acid. The yield of product, b. p. 160–168°, at 18 mm., was 60 g., or 62%.

2,6-Dibromohexanoic Acid.—The general procedure used was that described for the bromination of 5-bromopentanoic acid. From 25 g. of 6-bromohexanoic acid, 24 g. of dry bromine and 3 cc. of phosphorus tribromide, there was obtained 28 g., or 80%, of 2,6-dibromohexanoic acid; b. p., 158–160°, at 4 mm.; n_D^{21} , 1.5245, d_4^{21} , 1.7897; M_D , calcd., 47.09; found, 46.88.

Anal. Subs., 0.1954, 0.2492: 8.23, 10.49 cc. of 0.1737 *N* AgNO₃. Calcd. for C₆H₁₀O₂Br₂: Br, 58.39. Found: 58.53, 58.50.

Summary

1. Improved methods for the preparation of 5-bromopentanoic acid and 2,5-dibromopentanoic acid and their esters and acid chlorides have been described.

2. It has been shown that the earlier description of 2,6-dibromohexanoic acid is in error and the correct description of this compound has been given.

THE ALKALINE OXIDATION OF ALPHA-NITRONAPHTHALENE

BY JOHN H. GARDNER¹

RECEIVED MAY 11, 1927

PUBLISHED JULY 5, 1927

Since it has been known for a long time that in the oxidation of α -nitronaphthalene in an acid medium, 3-nitrophthalic acid is the principal product,² it seemed logical to expect that the oxidation with alkaline permanganate should yield a nitrophthalonic acid, which could be converted into 3- or 6-nitrophthalaldehyde acid by procedure analogous to that used by Fuson³ for the preparation of phthalaldehyde acid from phthalonic acid. On carrying out the oxidation, however, it was found that the nitrated ring was attacked.

¹ National Research Fellow in Chemistry.

² Beilstein and Kurbatow, *Ann.*, **202**, 217 (1880).

³ Fuson, *THIS JOURNAL*, **48**, 1093 (1926).

α -Nitronaphthalene was oxidized by alkaline permanganate according to the same procedure that was used by Fuson for the oxidation of naphthalene. The product was condensed with aniline producing a derivative which, by melting point and analysis, was found to be identical with that obtained from phthalonic acid. This was further confirmed by its decomposition into the aniline derivative of phthalaldehyde acid and the preparation from that of phthalaldehyde acid itself.

This is not so surprising as it appears at first sight, since a similar result has been obtained in the case of other positively substituted naphthalene derivatives. For example, Graebe has shown that in the oxidation of α -naphthoylbenzoic acid and 1,2-benzanthraquinone, the ring of the naphthalene residue attached to the carbonyl groups is oxidized.⁴ This reaction has been confirmed in the second case by Scholl and Schwinger, who also pointed out that in an acid medium 1,2-benzanthraquinone is oxidized to anthraquinone-1,2-dicarboxylic acid, thus showing a complete parallel with the oxidation of α -nitronaphthalene.⁵

The production of a pronounced yellow color on boiling a suspension of α -nitronaphthalene in a solution of sodium hydroxide indicates the possibility of a reaction between the two. At present, however, there is no information available to justify any conclusion as to the nature of the reaction.

Experimental Part

Oxidation of α -Nitronaphthalene.—To a boiling mixture of 43 g. of α -nitronaphthalene and 500 cc. of 0.5 *N* sodium hydroxide solution in a flask provided with a reflux condenser and an efficient mechanical stirrer, there was added in small portions a boiling solution of 212 g. of potassium permanganate in 1500 cc. of water, during a period of one and one-half hours. The mixture was maintained at the boiling temperature until half an hour after the last addition of permanganate. A little alcohol was then added to destroy any remaining permanganate, and the mixture cooled and filtered. The filtrate was acidified with 140 cc. of concd. hydrochloric acid and evaporated to 500 cc. One hundred g. of aniline was then added and the resulting solution heated on the water-bath for two hours. After cooling, the crystalline precipitate was filtered out and dried at room temperature. Drying at an elevated temperature was found to cause considerable decomposition. The yield was 67 g., or 74%.

After several recrystallizations from alcohol, using Norite the first time, the product melted at 162–164°, with decomposition.

All melting points recorded in this paper are corrected.

Fuson reports³ for the aniline derivative of phthalonic acid, 165°. A mixed melting point of the product from α -nitronaphthalene with the aniline derivative of phthalonic acid showed no depression.

Anal. Subs., 0.3397, 0.3549: 40.60, 40.00 cc. of 0.1016 *N* HCl; 16.55, 16.10 cc. of 0.1328 *N* NaOH. Calcd. for $C_{21}H_{19}O_4N_2$: N, 7.73. Found: 7.94, 7.60.

Decomposition of the Aniline Derivative Obtained from the Oxidation Product of α -Nitronaphthalene.—Twenty-two g. of the aniline derivative was suspended in

⁴ Graebe, *Ann.*, **340**, 249 (1905).

⁵ Scholl and Schwinger, *Ber.*, **44**, 2992 (1911).

150 cc. of sodium-dried xylene and boiled under reflux for one and one-half hours. On cooling, there was deposited 13.2 g. of a gray powder.

On boiling the decomposition product with alcohol, 4 g. of a gray powder, softening at about 259°, remained undissolved. A similar by-product was noted in the preparation of the aniline derivative of phthalaldehyde acid by Fuson's procedure.

The alcoholic solution, after treatment with Norite, on cooling, deposited almost microscopic, colorless needles; m. p., 178°. The aniline derivative of phthalaldehyde acid melted at 176–177°. A mixed melting point showed no depression.

Anal. Subs., 0.3770, 0.3320: 30.35, 30.20 cc. of 0.1016 *N* HCl; 11.10, 12.00 cc of 0.1328 *N* NaOH. Calcd. for $C_{14}H_{11}O_2N$: N, 6.22. Found: 5.98, 5.94.

Preparation of Phthalaldehyde Acid.—For the preparation of phthalaldehyde acid, 44 g. of the aniline derivative of phthalonic acid, obtained from α -nitronaphthalene, was decomposed as described above. The xylene was decanted as completely as possible, and the residue boiled under reflux with 350 cc. of 10% hydrochloric acid for one and one-half hours. After cooling, the solution was filtered from a small amount of insoluble material and extracted with ether. The ether was evaporated and the residue dissolved in water. After treatment with Norite, the solution was evaporated to dryness, as the attempt to induce crystallization failed. The residue melted at 96° and showed no depression in melting point when mixed with phthalaldehyde acid. The product was free from nitrogen.

Neutral equivalent. Subs., 0.4277, 0.4177: 20.95, 20.59 cc. of 0.1328 *N* NaOH. Calcd. for $C_8H_6O_3$: neut. equiv., 150. Found: 153.7, 152.8.

Summary

It has been shown that in the oxidation of α -nitronaphthalene by potassium permanganate in an alkaline medium, the nitrated ring is attacked.

A SYNTHESIS OF TAURINE

BY C. S. MARVEL, C. F. BAILEY AND M. S. SPARBERG

RECEIVED MAY 12, 1927

PUBLISHED JULY 5, 1927

Taurine, 2-amino-ethylsulfonic acid, is of considerable interest to the physiological chemist since it occurs in the tissues of various lower animals and in secretions of the higher animals. In the bile it is found combined with cholic acid as taurocholic acid. The probable source of natural taurine is the amino acid, cystine. This conversion of cystine to taurine has been carried out in the laboratory by Friedmann¹ but it does not furnish a practical method of preparation.

At present the common sources for taurine are ox bile² and the large muscle of the abalone.³ The first source gives a very low yield of the

¹ Friedmann, *Beitr. Phys. Path.*, **3**, 38 (1903).

² (a) Hammersten, *Z. physiol. Chem.*, **32**, 456 (1901); (b) Tauber, *Beitr. Phys. Path.*, **4**, 324 (1904).

³ Schmidt and Watson, *J. Biol. Chem.*, **33**, 499 (1918).

product, and large amounts of the starting material must be available if any considerable amount of taurine is needed. The second source is said to be very satisfactory and 74 kg. of the muscles will yield 362 g. of taurine.

Taurine has been synthesized by several methods. Kolbe⁴ converted isethionic acid, $\text{HOCH}_2\text{CH}_2\text{SO}_3\text{H}$, to 2-chloro-ethylsulfonyl chloride, hydrolyzed this product to 2-chloro-ethylsulfonic acid and obtained taurine from this by the action of aqueous ammonia. However, he was troubled with the separation of the taurine from the ammonium chloride. Anschütz⁵ has also used this general method.

Gabriel⁶ prepared taurine from ethylene imine and sulfur dioxide and from 2-mercaptothiazoline⁷ by oxidation with bromine water. More recently Reychler⁸ obtained taurine from bromo-ethylamine and ammonium sulfite. All of these methods require 2-bromo-ethylamine as a starting material and are not really useful for the preparation of any large amount of product.

Auzies⁹ reports the preparation of taurine by sulfonation of acetaldehyde with chlorosulfonic acid, followed by the formation first of the aldehyde ammonia, then of the imido compound and finally by reduction to the amino compound. The reactions are quite complex.

Some time ago Kohler¹⁰ mentioned that the sodium salt of 2-bromo-ethylsulfonic acid was easily obtained from ethylene bromide and sodium sulfite. No details of the reaction were given but a statement was made that the compound would be described later. However, a search of the literature has not revealed any further information concerning this compound. This seemed to be a suitable starting point for the synthesis of taurine, so the preparation was studied and found to run very smoothly and in yields of about 80%.

In the first attempts to convert sodium 2-bromo-ethylsulfonate into taurine a method very much like that described by Kolbe⁴ was used. 2-Bromo-ethylsulfonyl chloride was prepared and then hydrolyzed to the acid. The sulfonic acid was then treated with aqueous ammonia and after the reaction was complete the taurine separated by crystallization from dilute alcohol which readily held in solution the ammonium bromide produced in the reaction. The yields by this procedure were very low.

It was then found that the sodium salt or the 2-bromo-ethylsulfonic acid could be treated directly with aqueous ammonia to give a mixture

of taurine and sodium bromide from which pure taurine could be easily obtained by crystallization from about 80% alcohol. The yield of product is about 40–50%. Undoubtedly, a considerable loss occurs in the separation from the sodium bromide.

The reaction between aqueous ammonia and sodium 2-bromo-ethyl-sulfonate is much slower than might be predicted from the relative positions of the bromine and the sulfur atoms. Several days are required for the complete conversion of the bromo to the amino compound. This is in accord with the results of Helfrich and Reid,¹¹ who have shown that oxidation of dichloro-ethyl sulfide to the sulfoxide and sulfone produces compounds with less active chlorine.

Experimental Part

Sodium 2-Bromo-ethylsulfonate.—In a 5-liter flask fitted with a reflux condenser, mechanical stirrer and separatory funnel were placed 615 g. of ethylene dibromide, 1250 cc. of 95% alcohol and 450 cc. of water. The stirrer was started and the mixture was heated to boiling. To the well-stirred, boiling mixture a solution of 125 g. of sodium sulfite (anhydrous salt) in about 450 cc. of water was added through the separatory funnel over a period of about two hours. The solution was boiled under a reflux condenser for two hours after all of the sulfite solution had been added and then the condenser was set for distillation and the alcohol and ethylene bromide were distilled. The remaining water solution was poured into a large evaporating dish and evaporated to dryness on the water-bath. The sodium 2-bromo-ethylsulfonate was extracted from the sodium bromide and unchanged sodium sulfite with 2 liters of boiling 95% alcohol. On cooling the solution, most of the salt crystallized and the mother liquor was used for a second extraction of the residue. The product after one crystallization from alcohol was dried in an oven at 110°; yield, 165–190 g., or 78–90%.

This product may contain as much as 5–8% of sodium bromide, but this does no harm in the subsequent reactions. The amount of sodium bromide can be estimated by titrating a sample of the salt with standard silver nitrate solution.

The concentration of alcohol seems to be fairly important and poorer yields were obtained when it was changed in either direction. The large excess of ethylene bromide is necessary to avoid the formation of the disulfonic acid. By diluting the alcoholic solution distilled after the reaction is finished, it is possible to recover nearly 400 g. of ethylene bromide. The salt is slightly hygroscopic and should be dried in an oven in order to remove the last of the water.

2-Bromo-ethylsulfonyl Chloride.—In a 1-liter round-bottomed flask fitted with a stopper carrying a calcium chloride tube were placed 100 g. of sodium 2-bromo-ethyl-sulfonate and 100 g. of phosphorus pentachloride. The reaction proceeded quietly and the contents of the flask became semi-fluid. After the reaction seemed to have stopped, the mixture was heated on a steam-bath for about two or three hours to insure complete reaction. It was then cooled thoroughly in an ice-salt mixture and treated with about 500 cc. of ice water to dissolve the salts and decompose any excess of phosphorus pentachloride. The oily layer, consisting of the sulfonyl chloride and considerable phosphorus oxychloride, was separated and distilled under reduced pressure. The yield of light straw-colored product, b. p. 119–121° at 25 mm., was 62–70 g., or 64–71%.

Anal. (Stepanow). Subs., 0.4157: 39.59 cc. of 0.1 *N* AgNO₃. Calcd. for C₂H₄O₂ClBrS: 40.06 cc. D₂₀²⁰, 1.921; *n*_D²⁰, 1.5242.

¹¹ Helfrich and Reid, *THIS JOURNAL*, **42**, 1208 (1920).

The product has a disagreeable odor and is a lachrymator. It hydrolyzes rather easily in the presence of water.

Taurine from 2-Bromo-ethylsulfonyl Chloride.—Thirty-seven g. of the sulfonyl chloride was added to 600 cc. of cold water and allowed to stand until the oily layer disappeared. It was then evaporated under reduced pressure to remove the water and hydrogen chloride. The residue (usually about 25 cc.) was treated with 150 cc. of aqueous ammonia (d., 0.9) and allowed to stand for several days. Then the dark colored solution was boiled with decolorizing carbon (Norite), filtered and evaporated to 10–15 cc., until no odor of ammonia was perceptible. On the addition of 95% alcohol, taurine crystallized; yield, about 3.5 g., or 16%.

Anal. (Kjeldahl). Subs., 1.3706: 10.77 cc. of 1 *N* acid. Calcd. for $C_2H_7O_2NS$: N, 11.2. Found: 11.0.

The Reaction between Sodium 2-Bromo-ethylsulfonate and Aqueous Ammonia.—In order to find out the approximate rate of reaction between sodium 2-bromo-ethylsulfonate and aqueous ammonia, a weighed sample of the dry salt was dissolved in a large excess of aqueous ammonia and from time to time aliquot portions were titrated with standard silver nitrate solution to determine the amount of bromide ion. These experiments indicated that the reaction was about 25% complete in five hours, 60% complete in thirty hours and 90% complete in five days. The reaction did not seem to have proceeded further at nine days, so in subsequent experiments five days were allowed for this reaction.

The reaction between sodium 2-bromo-ethylsulfonate and ammonia might produce taurine and sodium bromide, or the sodium salt of taurine and ammonium bromide. In order to determine which products were produced, some samples of the sulfonic acid salt and ammonia were allowed to stand for five days and then evaporated to dryness. When all of the excess of ammonia had been driven off, the residue was analyzed by the Kjeldahl method. This residue would contain twice as much nitrogen if the sodium salt of taurine and ammonium bromide were formed as it would if taurine and sodium bromide were formed. The actual amount of nitrogen was always somewhat less than that required for the second reaction.

Taurine from Sodium 2-Bromo-ethylsulfonate.—A solution of 110 g. of sodium 2-bromo-ethylsulfonate (containing 5–6% of sodium bromide) in about 2 liters of concd. aqueous ammonia (d., 0.9) was allowed to stand for five to seven days and then evaporated to dryness. The last of the water was removed by heating on a steam-bath. The residue was dissolved in the minimum amount of hot water and, if necessary, treated with decolorizing carbon (Norite). The colorless solution was concentrated to 65–70 cc. and about four volumes of 95% alcohol were added. In a short time taurine mixed with some sodium bromide separated. When crystallization was complete, the crude taurine was collected on a filter and recrystallized by dissolving in hot water and then adding to the solution enough 95% alcohol to give a final concentration of 80% of alcohol. The taurine which then separated was usually free from bromides. However, occasional runs had to be recrystallized four or five times to remove all of the sodium bromide. The yield of pure taurine was 31 to 36 g., or 44–51%.

Summary

Taurine, 2-amino-ethylsulfonic acid, has been prepared in fair yields by converting ethylene bromide to sodium 2-bromo-ethylsulfonate and treating this product with aqueous ammonia.

THE INFRA-RED ABSORPTION SPECTRA OF ORGANIC DERIVATIVES OF AMMONIA. V. PRIMARY, SECONDARY AND TERTIARY ALKYL AMINES

BY FREDERICK K. BELL¹

RECEIVED MAY 16, 1927

PUBLISHED JULY 5, 1927

Introduction

All of the ammonia derivatives thus far examined in this series of studies² contained the aryl group and, with the exception of the phenyl amines and naphthylamine, were of the mixed aryl-alkyl type.

The present communication is concerned with the examination of the purely aliphatic amines. It was hoped that the results of this investigation, in conjunction with those already obtained in the case of the pure aryl amines, would be of assistance in the interpretation of the absorption spectra of the mixed amines previously examined. This expectation has been at least partially fulfilled.

The absorption spectra, between 1.0 and 12.0 μ , of three series (*n*-propyl, *n*-butyl and *iso*-amyl) of primary, secondary and tertiary amines are presented and discussed in this communication.

Experimental Part

The same experimental procedure as previously described has been followed in the present work. Since all of the substances examined are liquids, the measurements were made at room temperature. In this connection it appears desirable to mention a precaution which should be taken in the examination of liquids in the open type of absorption cell as employed in this work. Considerable evaporation of the liquid may take place depending, of course, on the boiling point of the liquid in question, and liquid must be added from time to time in the course of the examination. This procedure was found to be necessary in the case of several compounds in the present study.

The specimens of mono-, di- and tri-*n*-propylamine, mono-, di- and tri-*n*-butylamine and mono-, di- and tri-*iso*-amylamine were obtained from

¹ E. R. Squibb and Sons Fellow.

² Bell, *THIS JOURNAL*, (a) **47**, 2192, 3039 (1925); (b) **48**, 813, 818 (1926).

the Eastman Kodak Company. They were labeled "highest purity" and were used as obtained in original glass-sealed containers.

The absorption spectra of these compounds are shown graphically in Figs. 1 to 9, in which the percentage transmission has been plotted against the wave length in microns. In every case the thickness of the absorbing layer was 0.025 mm., as indicated on each curve by the value of T .

Discussion

The infra-red absorption spectrum of only one of the simple alkyl amines has been recorded in the literature, namely, triethylamine, in Coblenz' monograph.³

Fig. 1.—*n*-Propylamine; $T = 0.025$ mm.

The curves in Figs. 1 to 9 show certain general similarities. The general transparency of the nine substances is of the same order of magnitude, with the possible exception of di-*n*-butylamine. However, between 10.0 and 12.0 μ the three mono derivatives (Figs. 1, 4 and 7) show a marked similarity in opacity, as contrasted with the relatively high degree of transparency of the other derivatives in the same region. No definite influence which can be attributed to increase in molecular weight is to be noticed.

³ Coblenz, *Carnegie Inst. Pub.*, 35, 63 (1905).

In the region of 3.45μ , the characteristic band of the methyl group is sharply defined in each case with marked regularity in intensity. Similarly, in each curve there appears a band of diminished intensity at 6.85μ . Coblentz found this band in numerous compounds of different chemical structure. If we assume an harmonic relation between this band and the 3.45μ band, its presence is to be attributed to the same origin, that is, the methyl group.

It will be noticed also that a sharply defined band appears in each curve in the region of 7.25μ , its position varying from 7.2 to 7.3μ . With the possible exception of a band appearing with a fair degree of constancy

Fig. 2.—Di *n*-propylamine, $T = 0.025$ mm.

in the region of 9.3μ , no consistent similarity of the absorption curves is apparent in the longer wave lengths. This 9.3μ band was found consistently by Coblentz in his examination of petroleum distillates.³

As in the case of all of the ammonia derivatives which have been previously examined, the region between 3.0 and 4μ is of particular interest in the present study also. As has been noted above, the 3.45μ band remains strikingly constant in intensity, which appears to be independent of the molecular weight of the substituent alkyl group and also the number of hydrogen atoms of the ammonia molecule which have been substituted.

In the three primary amines (*n*-propyl, *n*-butyl and *iso*-amyl), the ammonia band is sharply resolved at 3.05μ , its intensity being less than

that of the 3.45μ band in each case. In the secondary amines (Figs. 2, 5 and 8), its location remains unchanged but its intensity is markedly decreased. This band has practically disappeared in the curves for the three tertiary amines (Figs. 3, 6 and 9) and is also absent in Coblenz' curve for triethylamine.

It is thus seen that the qualitative differentiation between primary and secondary and tertiary amines, as previously found, is valid in the case of the alkyl amines.

Fig. 3—Tri-*n*-propylamine; $T = 0.025$ mm.

Salant⁴ has examined the absorption spectra of di- and tri-*n*-propylamine, di- and tri-*n*-butylamine and di- and tri-*iso*-amylamine in the restricted region of 2.5 to 4.0μ . In that region of the present curves, there is good agreement with his measurements. It is apparent, however, that Salant used considerably thicker layers of the absorbing materials than those employed in the present study.

Another region of interest in the absorption spectra of the alkyl amines is at 6.25μ . In an earlier communication it was suggested that the^{2a} deep ammonia band, which Coblenz locates at 6.1μ , was also present in the spectra of organic derivatives of ammonia. It was pointed out that the absorption in that region cannot be readily interpreted when the benzene nucleus is present, since that nucleus has a characteristic ab-

⁴ Salant, *Proc. Nat. Acad. Sci.*, **12**, 74 (1926).

sorption at 6.25μ . In the present curves it is to be expected that the conditions in that region are greatly simplified.

In the case of the three primary amines (Figs. 1, 4 and 7) a well-defined band appears at 6.25μ , while the secondary and tertiary amines in Figs. 2, 3, 5, 6, 8 and 9 (and also in Coblenz' curve for triethylamine) show very little or no characteristic absorption at that point. There is, therefore, a marked diminution in the intensity of this band in passing from the primary to the secondary alkyl amine, but a slight change or none is to be noticed in the transition from the secondary to the tertiary amine; the examination of thicker layers of these substances might reveal a more pronounced difference.

Fig. 4—*n*-Butylamine; $T = 0.025$ mm.

Salant, assuming the presence of the 6.1μ ammonia in amines,⁴ suggests that the 3.0μ ammonia band is the first harmonic of the 6.1μ band. Ellis,⁵ on the other hand, has shown, from his examination of aniline and ten mono- and dialkyl anilines as far as 2.8μ , that absorption bands occurring at 1.47μ and 1.04μ are characteristic of the nitrogen to hydrogen bond and that the vibrations corresponding to these two bands and that at 2.8μ , as found by the present author in an examination of the same compounds, form a three-membered parabolic series.

If we assume a shifting of the 6.1μ ammonia band to 6.25μ , the absorp-

⁵ Ellis, *THIS JOURNAL*, 49, 347 (1927).

tion curves of *n*-propyl, *n*-butyl and *iso*-amylamine confirm Salant's hypothesis. However, a more thorough examination of the secondary and tertiary alkyl amines in this region will be necessary in order to demonstrate definitely the presence or absence of characteristic absorption.

For present purposes, the significance of the 6.25μ band is quite definite. The absorption in this region permits a ready differentiation between mono-alkyl amines and di- or tri-alkyl amines. This differentiation should be especially useful in the examination of those compounds which contain the hydroxyl group, which has a pronounced characteristic absorption at 3.0μ . An instance of the complications that may exist in this region (3.0μ) is shown by the author's absorption curves of the alkaloids containing the tropan nucleus.⁶

Fig. 5.—Di-*n*-butylamine, $T = 0.025$ mm.

Since the publication of the preceding paper of this series, it has come to the author's attention that a number of pertinent communications by Bonino had been inadvertently overlooked. Bonino⁷ suggests that the absorption occurring between 2.5 and 3.9μ is caused by linear oscillators formed of hydrogen atoms which oscillate around their position of equilibrium. If the hydrogen is united to one atomic species, for

example, carbon, oxygen or nitrogen, a simple band of constant location results, as in methane, water or ammonia. On the same basis, we should expect the presence of two bands in this region for such compounds as methyl alcohol or methylamine.

In his examination of the infra-red absorption spectra of halogen derivatives of ethylene and ethane (in which the number of carbon atoms is constant), Bonino found that the absorption band was always at 3.51μ . Its intensity varied, however, and it was entirely absent in tetrachloroethylene and hexachloro-ethane; furthermore, he observed that the coefficient of maximum absorption of this band follows quantitatively the variation in the number of hydrogen atoms, independently of the number of carbon atoms present. The exact location of this band in compounds of different chemical composition is determined, according to Bonino, by intermolecular action.

That these conclusions, developed by Bonino specifically for the case of the carbon to hydrogen bond, are likewise applicable to the nitrogen to hydrogen bond, as suggested by him, appears to be substantiated, at least qualitatively, by the experimental data of this series of studies. Preliminary work by the present author on the examination of some alkyl and aryl mercaptans, sulfides and disulfides points to a similar behavior for the hydrogen to sulfur bond.

Summary

1. The infra-red absorption spectra of mono-, di- and tri-*n*-propylamine, mono-, di- and tri-*n*-butylamine and mono-, di- and tri-*iso*-amylamine have been examined between 1.0 and 12.0μ .
2. The qualitative differentiation between primary and secondary and tertiary amines, by means of the intensity of the characteristic absorption band in the region of 3.0μ , has been found to be valid in the case of the alkyl amines.
3. Primary alkyl amines may be qualitatively differentiated from secondary or tertiary alkyl amines by the absorption in the region of 6.2μ . The significance of this differentiation, which fails in the presence of the aryl group, has been indicated.

BALTIMORE, MARYLAND

NOTES

A Grignard Starter.—Very often when preparing a Grignard reagent, addition of the halide fails to start the reaction. This is true of readily prepared reagents.

The writer has been quite successful in touching off such reaction mixtures by adding a small grain of anhydrous aluminum bromide. The bromide is quickly prepared by warming a few grains of aluminum in a

dish and pouring in some bromine, again warming to volatilize the excess. The mixture glows and fumes and the product must be used immediately. Anhydrous aluminum chloride¹ has also been successfully employed a few times.

The method has not been applied to any of the very difficult preparations.

The Chloromethylacetophenones.—In connection with some work on the condensation of benzil and substituted acetophenones, we have had occasion to prepare the 2-chloro-5-methyl and 4-chloro-3-methyl derivatives from *p*-chlorotoluene and *o*-chlorotoluene, respectively. These ketones have been reported once previously by Claus.¹ He made them by the action of acetyl chloride on the chlorotoluene in the presence of anhydrous aluminum chloride; his yields were very poor and the ketones boiled over a considerable range; furthermore, he did not analyze them because he realized they were impure. He made the oximes, however, and proved the structure of the ketones by oxidation to the corresponding chlorotoluic and chlorophthalic acids.

By the use of acetic anhydride instead of acetyl chloride² we have obtained the ketones nearly constant boiling after one distillation, the 3-chloro-4-methyl derivative in a yield of 70% and the 2-chloro-5-methyl derivative in a yield of 34%. Claus had great difficulty in preparing even small amounts of the latter. We have determined the boiling points and refractive indices of both the ketones; they distil without decomposition at atmospheric pressure, forming colorless oils that very slowly take on a yellow tinge in the light. They have a very faint odor suggestive of acetophenone.³

NEW BOOKS

Old Chemistries. By EDGAR F. SMITH, University of Pennsylvania. McGraw-Hill Book Company, Inc., 370 Seventh Avenue, New York City, 1927. xi + 89 pages, 32 illustrations. 26 × 18.5 cm. Price \$2.50.

The chemists who have had the good fortune to read this latest volume by Professor Smith have no doubt been tempted, as was the reviewer, to alter the old familiar motto of Alonzo of Aragon into "Old wood to burn, old wine to drink, old friends to trust and old chemistries to read." It is indeed just such a book as one would delight to discuss with a well-trying friend on a wintry evening when the wood fire is blazing merrily and while there is still left, perchance, a little of the precious vintage of former days.

Those visitors, who have penetrated to the innermost sanctum of Professor Smith's office, with its priceless collection of old chemistries and prints and with its scores of framed portraits of chemists looking down from the walls like a cloud of witnesses, know that there is no more fascinating hobby than the pursuit in leisure hours of the cultural side of one's vocation. Professor Smith's object, as modestly stated in his preface, is "to lay before interested readers a hint of the vast stores of early literature relating to chemistry." The book, however, is more than a hint and might almost be termed an anthology, so varied and so interesting are the selections to which the reader's attention is called. Some fifty authors are cited whose published works extend over a period of three centuries, from an edition of Geber printed at Nuremberg in 1545 down to the "Muck Manual" of Samuel L. Dana, printed at Lowell, Massachusetts, in 1842. In addition to ancient works upon alchemy, there are mentioned old treatises, histories, catechisms, conversations, compendia, epitomes, manuals, systems, elements, essays, lectures, dissertations and philosophies of chemistry—a list so general and comprehensive that every chemist, no matter how specialized, will find much to attract his interest. The references to these volumes are enlivened by the sympathetic comments of the author as he opens his treasures before us and calls our attention to this or that passage or illustration. The company to which the reader is admitted is a select one, including not only European celebrities, such as Black, Bergmann, Fourcroy, Lavoisier, Chaptal, Orfila, Parkes, Thomson and Accum, but early American authors such as Rush, Ewell, Macneven, Gorham, Bache, Silliman, Hare and others. The well chosen illustrations of apparatus, title-pages, lecture cards, chemists, etc., lend additional interest to the volume. There are portraits which, once seen, the reader will never forget, such as the cherub face of Boerhaave and the delightful antique of Mrs. Marcet in lace cap and curls. There are also letters, such as the historic message of Lavoisier to Franklin and the charming congratulatory note of John Adams to Gorham which, once read, will stimulate a second and a third perusal.

It is not for correct theories or practical values that we consult the old chemistries which Professor Smith has placed before us, but for a draught of the spirit and enthusiasm with which these works were written. Such, for example, was the glowing zeal of the young Philadelphian, John Pennington, who was stricken by yellow fever in 1793 at the early age of 25, and the title-page of whose "Chemical and Economical Essays" is reproduced in the present volume.

On the first page of his book Professor Smith laments "that in these days of action little patience is had with tales of the past." Posterity, however, will have its revenge for there will be even less of patience a century hence with the chemistries of today. It was Emerson, the wisest of American critics, who wrote that "science must be studied humanly" and it is for the lack of this human element that chemistry is suffering at the present time. The chemists of America may most truly be thankful to Professor Smith that by the single example of this new volume he has refuted the charge of European critics that chemistry in America is wholly industrialized. There are many in this country who believe that chemistry has higher messages than those of industrial benefits—"messages in history, in philosophy, in economics, in social relations, in art, in international relations, in literature and in a wide and extensive culture," to quote from the concluding sentence of Professor Smith's new book. To all chemists, and especially to those who believe in these other messages, the present volume upon "Old Chemistries" is most cordially recommended.

C A BROWNE

Recent Advances in Physical and Inorganic Chemistry. By ALFRED W. STEWART. D.Sc., Professor of Chemistry in the Queen's University of Belfast Fifth edition, Longmans, Green and Company, 55 Fifth Avenue, New York, 1926. xi + 312 pp. 35 figs. 22 × 14 cm. Price \$6 50.

Some seven years have elapsed since the publication of the last (fourth) edition of this book. The author has, therefore, been obliged practically to rewrite it. Only five chapters have survived with minor alterations; twelve new chapters have been added and a corresponding number of chapters in the old edition eliminated. These new chapters deal with hafnium, isobars, the results of mass-spectrography, the segregation of isotopes, the structure of the atom, active hydrogen and nitrogen, some new hydrides, the effect of intense drying and Tesla-luminescence spectra.

These subjects are presented with the same clarity and enthusiasm which characterized the earlier edition. The book represents a useful and valuable digest of the recent progress in the fields which it attempts to cover.

ARTHUR B. LAMB

Physico-Chemical Metamorphosis and Some Problems in Piezochemistry. By ERNST COHEN, University of Utrecht. The George Fisher Baker Non-Resident Lecture-ship in Chemistry at Cornell University. McGraw-Hill Book Company, Inc., 370 Seventh Avenue, New York City, 1926. 190 pp. 58 figs. 23.5×15.5 cm. Price \$2.50.

In the introductory lecture to the series of twenty-one discourses which make up this volume, Professor Cohen quotes from the French savant "Ce n'est pas assez de savoir les principes, il faut savoir manipuler." The book shows that the author has indeed taken this to heart. With charming style and very simply he lays forward and illustrates by examples the principles of polymorphism and some of the problems dealing with the behavior of chemical systems under pressure. At the same time he misses no opportunity of enlarging on those details of experimental technique for which the Laboratory at Utrecht is justly famous. His developments of the electrical methods for investigation of transition points, solubilities, etc., are particularly worthy of notice.

The object of the book may be stated in the author's own words. "It is my purpose to tell you systematically what external conditions of temperature, pressure, solvent, etc., cause the formation of modifications of the same substance and what consequences their existence will have." We think he has succeeded. No one can read the first half of the book without having his ideas of the sanctity of physico-chemical constants and of the nature of matter very salutarily shaken.

The book is easily read and will appeal to all students of physical chemistry; in particular, teachers of the subject should find it very inspiring. Like most series of lectures, however, it deals more with the aspect of the subject as viewed by the author than with the subject as a whole. Hence, its main use to the specialist in the field is as an index to the work of the Utrecht school.

The book is well printed, adequately illustrated and indexed, and the few typographical errors are unimportant.

R. E. GIBSON

Anorganische Chemie. (Inorganic Chemistry.) By Dr. ROBERT SCHWARZ, Professor of Inorganic and Analytical Chemistry at the University, Freiburg. Theodor Steinkopff, Dresden and Leipzig, 1927. xi + 139 pp. 22×15 cm. Price, unbound, M. 8; bound, M. 9.20.

This is a further volume in the series of monographs edited by Dr. Liesegang designed to summarize the progress of research in the various fields of natural science since 1914. Earlier volumes in this series have already presented some features of the progress in inorganic chemistry; for instance, Physical Chemistry, by Benrath; Colloidal Chemistry, by Liesegang; Mineralogical Chemistry, by Eitel; and Atomistics, by Gerlach.

The present volume is particularly concerned with *experimental* inorganic chemistry.

Each element is separately discussed, the order being that of the periodic system. This discussion occupies three quarters of the volume. There are in addition a short chapter devoted to such general topics as the concept of an element, the color of inorganic compounds and the hydrogen compounds of the elements, and another on complex compounds.

In a more convenient form but less complete, this volume covers substantially the same ground as do the "Annual Reports" of the Chemical Society of London in their chapters on Inorganic Chemistry.

ARTHUR B. LAMB

Die Welt der Atome. Zehn gemeinverständliche Vorträge. (The World of Atoms. Ten Popular Lectures.) By Dr. ARTHUR HAAS, Professor of Physics at the University, Vienna. Walter de Gruyter and Company, Berlin, W10, Germany, 1926. xii + 130 pp. 37 figs. 23.5 × 15 cm. Price, unbound, M. 4.80; bound, M. 6.

This book contains, in printed form, a series of lectures delivered to a general audience at the University of Vienna in 1926. The book starts with a short discussion of the Philosophy of Democritus and the first chapter presents some of the general ideas of the atomic theory with the lines of supporting evidence. The structure of electricity and the means of determining the absolute masses of the atoms are clearly discussed. The second chapter discusses the "building stones for atoms." Prout's hypothesis is mentioned and the chapter gives a rapid discussion of cathode rays, alpha-ray tracks, positive-ray analysis and atomic disintegration by alpha-particle bombardment. The following chapters take up in succession "Light Quanta," "Spectra and Energy States," "The Hydrogen Atom," "Elements," "The Atom as a Planetary System," "Molecules," "Radioactivity" and "Transmutation of the Elements."

The author has made a sincere attempt to bring the material included up to date. For example, illinium is included in the list of elements, and the work by Millikan and his co-workers on "stripped atoms" is discussed. The Bohr theory is accepted frankly as the best picture we have of the structure of atoms. The author might be criticized for not stating some of the objections to this theory. In general, the author has included impartially the important pieces of work in the various fields, although the list of workers is necessarily not complete. It might seem somewhat of a mistake not to mention any American contributions in such fields as the determination of the velocity of light, the determinations of the atomic weight of lead from radio-active minerals, the separation of isotopes by diffusion and positive-ray analysis, since other work, frequently not as accurate, is included.

A reader who had had no previous contact with the ideas presented

in the book might find it difficult reading. Any one who has some knowledge of the trend of physics will find the book useful in presenting a connected and logical picture of current ideas. The author has sacrificed rigor for ease of presentation in a few instances but, on the whole, the book is remarkably free from the sort of looseness so frequently encountered in popular treatments of this subject.

W. ALBERT NOYES, JR.

Der Bau der Atome und das periodische System. (The Structure of Atoms and the Periodic System.) By IVAN KOPPEL, Professor at the University, Berlin. Leopold Voss, Leipzig, 1927. vi + 174 pp. 47 figs. 22 5 × 14 5 cm. Price, unbound, M. 9, bound, M. 10.50.

This is a brief attempt to recount and interpret for chemists or for students of chemistry some of the results of modern atomic physics. The author recognizes the necessarily arbitrary nature of the task of selecting material of special importance and interest for chemists, but hopes at least to have removed certain hindrances to the entrance of chemists into this field of study.

Subatomic physics is introduced by a short history of the periodic system, atomic and kinetic theory. The author then lists the principal facts which have led to modern extensions of Dalton's views, and begins his systematic discussion of them with radio-activity. Then follows the action of alpha particles on matter, and the researches on positive rays which have revealed the isotopy of non-radio-active elements and so profoundly influenced our present ideas of the meaning of "an element."

The next chapter deals with x-rays, Moseley's law and the simplified theory of the hydrogen atom as well as the calculation of the constants of Moseley's equation for x-ray emission frequencies. A simple account of "hydrogen-like" spectra introduces the effect of the mass of the nucleus on the motion of the system. In the next chapter the Hamiltonian equations are employed and permit a more general statement of the quantum conditions; then follow elliptical orbits, Stark and Zeemann effects and the relativity mechanics. In the last chapter the reader learns of the speculations of Kossel, Bohr, Stoner and Swinne, concerning the ordering of the non-nuclear electrons. V. M. Goldschmidt's geochemical ideas are mentioned. The treatment follows Sommerfeld in most respects but the material is greatly restricted and simplified. The condensation is excellently done. The reviewer was disappointed not to find more on the nature of non-hydrogen-like spectra, magnetic properties, and also some account of the ion-lattice theory of crystals.

NORRIS F. HALL

Colloids: A Textbook. By H. R. KRUYT, Professor of Physical Chemistry, University of Utrecht. Translated from the Manuscript, by H. S. VAN KLOOSTER, Professor of Physical Chemistry, Rensselaer Polytechnic Institute, Troy, N. Y. John Wiley and Sons, Inc., 440 Fourth Avenue, New York City, 1927. xi + 262 pp. 116 figs. 23.5 × 15.5 cm. Price \$3.50.

The author states that his purpose is "to offer a main line of orientation to students who wish to become acquainted with the general trend of colloid chemistry, or who desire to undertake research in this particular branch of chemistry." This purpose has been attained for the most part in so far as his limited space allows. The treatment is divided into four sections; General Methods, Suspensoids, Emulsoids, Special Cases. The treatment of suspensoids is quite the conventional one, although not all of his readers will agree that the dyeing of wool is an example of reversible adsorption and that fastness of dyed fabrics to washing depends upon adsorption equilibrium (p. 38). Langmuir's views on adsorption are questioned on page 28 and adopted on page 103.

In the treatment of emulsoids the author differs sharply from Loeb's ideas. An emulsoid sol consists of particles surrounded by a film of water which protects them against flocculation, chiefly by hydration. The protein emulsoid sols also possess an electrical double layer, one constituent of which originates in the particle itself. The Donnan equilibrium is presented in the usual way and a theory of gelatinizing is presented in considerable detail. Soaps are considered as colloids intermediate between suspensoids and emulsoids. McBain's theory of the ionic micelle is considered superfluous. The colloidal soap particle consists probably of salt molecules, only those on the outside being ionized and taking part in the electrical double layer.

The translator deserves the highest commendation for his skill in rendering a foreign language into English. This task has been accomplished with the complete elimination of foreign idiom, so that the text as presented reads as if it were originally written in English.

F. B. MILLARD

Einführung in die Chemie der Polymeren Kohlenhydrate: Ein Grundriss der Chemie, der Stärke, des Glykogens, der Zellulose und anderer Polysaccharide. (Introduction to the Chemistry of Polymeric Carbohydrates: An Outline of the Chemistry of Starches, Glycogens, Cellulose and other Polysaccharides.) By P. KARRER, Professor at the University, Zürich. Akademische Verlagsgesellschaft m.b.H., Leipzig, 1925. ix + 285 pp. 21.5 × 15 cm. Price, bound, 16 Mk.; unbound, 13 Mk.

In this treatise the author gives a critical review of recent work on the chemistry of starch, glycogen, cellulose and related polysaccharides.

The seven chapters comprise (1) starch, (2) glycogen, (3) lichenin, (4) cellulose, (5) inulin, (6) chitin and (7) other polysaccharides (pentosans, hexosans).

The topics are treated throughout from the physico-colloidal standpoint, and views of other workers are reviewed critically and impartially.

The author's valuable personal contributions to this field are well known and it is this intimate, personal contact which has enabled him to portray with remarkable clarity and originality the properties of these natural compounds and the intimate relationship existing between them.

The volume can be heartily recommended to all workers in the field of polysaccharide chemistry.

HAROLD HIBBERT

Problems in Organic Chemistry. By H. W. UNDERWOOD, JR., Ph. D., Instructor in Organic Chemistry, Massachusetts Institute of Technology. McGraw-Hill Book Company, Inc., 370 Seventh Avenue, New York, 1926. x + 233 pp. 21 × 14 cm. Price, \$2.00.

Far too large a part of the instruction in science in our colleges and universities consists in filling the minds of students with facts which they are expected to remember. It is much more important that they should be taught to use the facts at their command and the knowledge available in textbooks and handbooks in a constructive way. This is particularly true of organic chemistry. The facts of the science are almost unlimited in number and the most conscientious student can retain only a few in his memory. As our author well says, "Descriptive questions which involve merely a restatement of the material in textbooks or lecture notes have little or no value in teaching students how to master the principles of the subject and apply them to concrete cases."

Dr. Underwood's book is well adapted to remedy this defect in the ordinary teaching of organic chemistry. In each of the twenty-four chapters after the first two a brief statement is given about the characteristics and nomenclature of some class of organic compounds and, in nearly all, there are charts showing the most important relations to other classes of compounds. Then follow numbered paragraphs, each containing from one to eight or ten problems or questions. The distinction between problems which the student should be able to solve from his knowledge of the subject and questions which involve detailed knowledge to be found in textbooks or handbooks is not kept as clear as it might have been and some of the paragraphs resemble a quiz-compend rather than genuine problems. The design of the book is certainly very excellent and it will prove very useful both to students and teachers.

The question might be raised, of course, whether such problems would not find their place better in a comprehensive textbook of organic chemistry but so long as the textbooks in common use do not provide such problems, such a book is timely.

In reading the discussions of nomenclature, one is impressed with the chaotic state of the subject and it would have been well if the author

had paid closer attention to the principles followed by *Chemical Abstracts*, the best authority we have in English. Nomenclature is, after all, a matter for authority and not for the exercise of personal idiosyncracies.

It may not be out of place to remark that the exact atomic weight of carbon, 12.005, is quite unnecessary in calculating the analyses of organic compounds. The factor 3/11 for the carbon of carbon dioxide is sufficiently accurate even for very accurate determinations. Even the value 1.008 is scarcely necessary for hydrogen. If 1 is taken for hydrogen and 1/9 of the weight of water found is taken as the weight of the hydrogen found, two errors which very nearly compensate each other are introduced and the results are well within the errors of ordinary analyses.

W. A. NOYES

A Text-Book of Organic Chemistry. Historical, Structural and Economic. By JOHN READ, Professor of Chemistry, University of St Andrews G Bell and Sons, Ltd, London, 1926. xii + 680 pp 87 figs 19.5 × 13 cm Price, 12s 6d net.

"The treatment of the subject has been stripped of a good deal of detail which is often included in a preliminary account, but which is here replaced by other matter illustrating in broad outline the scope of organic chemistry, its position as a link between physical and biological science and its industrial and economic interest. In accordance with the same principle, the chemistry of the fats, carbohydrates, proteins and other important natural groups has received an unusual prominence in the scheme of presentation. These readjustments of emphasis have been effected with little compunction, in the belief that a beginner in organic chemistry should be encouraged to utilize his available time and energy in obtaining a comprehensive view of the science and in absorbing its spirit and general principles, rather than in 'learning' lists of specialized reactions and inter-relationships."

The reviewer has had the book on his desk an inordinate time—certainly long enough to give it a very thorough reading. All of the book has not been read. However, enough of it has been read to warrant the following observations. It is an excellent book, one of the best of its kind; it is unusually free from typographical errors, and the format is good.

Undoubtedly many in this country will object to giving the first 60 pages to an historical development of chemistry. Few will deny that these early chapters are interestingly presented. The author in his preface makes a good pedagogical case for the inclusion of the historical matter. It is not an overly serious matter if all the students do not read all of the historical development at this stage of their training. There would still be left a large number of pages of excellent material.

THE POTENTIAL OF THE GOLD-AURIC OXIDE ELECTRODE

BY ROSCOE H. GERKE AND M. DOROTHY ROURKE

RECEIVED SEPTEMBER 7, 1926

PUBLISHED AUGUST 5 1927

The original purpose of this investigation was to study the properties of the gold-aurous oxide electrode. The authors, however, were entirely unsuccessful in preparing aurous oxide by duplicating the methods described in the literature or by any other methods which suggested themselves. During the course of the investigation it was observed that the potential of the gold-auric oxide electrode was about the same as that reported in the literature for the gold-aurous oxide electrode.¹ Hence, it is the purpose of this paper to present the results of the experiments on the gold-auric oxide electrode and to present briefly the experimental facts which lead to the conclusion that it is doubtful whether aurous oxide has ever been prepared.

The Gold-Auric Oxide Electrode

The cell, $\text{Hg(l)}, \text{Hg}_2\text{SO}_4(\text{s}), \text{H}_2\text{SO}_4, \text{Au}_2\text{O}_3(\text{s}), \text{Au (cryst.)}$ was employed in the measurement of the potential of the gold-auric oxide electrode. The cell consisted of two half-cells² with side arms dipping into a small beaker containing sulfuric acid of the same concentration as in the half-cells. Thus, the cell contained no liquid potential. The electromotive force measurements were made with a Leeds and Northrup student potentiometer and galvanometer at room temperature, which was about 25° . With this apparatus the electromotive force could be read easily to a millivolt, which is sufficiently precise for cells containing gold electrodes.

The auric oxide was prepared by the method of Krüss.³ The gold was

¹ Campbell, *Chem. News*, **96**, 257 (1907).

² Sherrill, "Laboratory Experiments on Physico-Chemical Principles," The Macmillan Company, 1923.

³ Krüss, *Ann.*, **237**, 291 (1887).

precipitated by the reduction of auric chloride solution with sulfur dioxide solution. The gold appeared as thin crystals. The gold-auric oxide half-cell was constructed in the following manner. The gold crystals mixed with an equal amount of auric oxide in sulfuric acid solution were introduced into the electrode vessel. A dip electrode consisting of a glass tube with a platinum wire sealed through the end made electrical contact with the gold. The results on cells with three concentrations of sulfuric acid are given in Table I.

TABLE I		
POTENTIAL OF THE GOLD-AURIC OXIDE ELECTRODE AT 25°C.		
Concn., H ₂ SO ₄	Volts	Volts
0.0506	0.599 ± 0.002	1.353 ± 0.002
1.031	0.629 ± .002	1.367 ± .002
1.031	0.690 ± .001	1.365 ± .002

The electromotive force of the cells increased for about 24 hours and after that time it was constant within the limits given in Table I, Col. 2, whether the cells were agitated or not. The first column in Table I gives the concentration of the sulfuric acid in formula weights per 1000 g. of water. Cols. 2 and 3 are, respectively, the electromotive force of the cells, Hg(l), Hg₂SO₄(s), H₂SO₄, Au₂O₃(s), Au (cryst.) and H₂ (1 atm.), H₂SO₄, Au₂O₃(s), Au (cryst.). The values for the electromotive force⁴ of the latter cell were calculated from the observed values in Col. 2, and from values of the electromotive force of the cell, H₂ (1 atm.), H₂SO₄, Hg₂SO₄(s) Hg.⁵

From the average of the values in Col. 3, the potential of the gold-auric oxide electrode, Au (cryst.), Au₂O₃(s) H⁺ is -1.362 volts, which is somewhat larger than Campbell's value, of about -1.2 volts for the gold-aurous oxide electrode, Au, Au₂O(s), H⁺. This latter value is corrected neither for liquid-junction potential nor by activity coefficients.

The value 18,810 cal. for the free energy of formation of auric oxide has been computed from the electromotive force of the cell in Col. 3 for the change of state, 3H₂ + Au₂O₃(s) = 2Au (cryst.) + 3H₂O(l). The dissociation pressure, 1.46 × 10⁹ atmospheres shows that auric oxide is very unstable with respect to the elements at room temperatures.

Aurous Oxide

There is no *a priori* reason why aurous oxide can or cannot be made. The necessary conditions for its preparation are: (1) a chemical reaction with a negative free energy increase and (2) the rate of decomposition of the substance, once prepared must be slow.

The methods which were employed to prepare aurous oxide will be

⁴ The conventions as to sign of electromotive force are the same as those of Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923.

⁵ Randall and Cushman, *THIS JOURNAL*, **40**, 393 (1918).

mentioned very briefly. The investigators who report analyses of their product are Figuier⁶ and Krüss.⁷ Both of these methods of preparation were tried. Both preparations had the appearance given in the descriptions, but the microscope revealed the presence of metallic gold. The method used by Campbell¹ was tried with the same results. Furthermore, the boiling of auric chloride with potassium hydroxide solution, the direct reduction of auric oxide by sulfur dioxide solution, and the treatment of aurous iodide with acids and bases did not give a product which was free from metallic gold.

In addition, Hartung⁸ has made a very thorough study of methods of preparation of aurous oxide. He observed that chemical analysis is not sufficient evidence to prove whether a given preparation is aurous oxide or not. He found that his preparations contained metallic gold and concluded that "No evidence has therefore been obtained to show that aurous oxide exists; its chemical and physical properties are those of a mixture of gold and auric hydroxide."

Finally, Buehrer⁹ made a preparation by a method adapted from that of Krüss,⁷ which was employed with crystalline gold as a gold-gold oxide electrode. This electrode when compared with a hydrogen electrode in sulfuric acid solution gave an initial value of about +1.1 volts. After two years the electromotive force had increased to +1.363 volts. This result can be interpreted in two ways; one in which it is assumed that aurous oxide is thermodynamically more stable than auric oxide, in which case the electrode initially consisted of Au (crystalline), Au₂O (solid), H⁺; and second, which the present writers have suggested, in which it is assumed that aurous oxide did not exist in the blue-black precipitate in the electrode and that the electrode consisted initially of Au (colloidal), Au₂O₃ (solid), H⁺. If the colloidal gold slowly changed to crystalline gold, the electromotive force would increase to the value 1.363 volts. The latter assumption has in its favor the fact that the blue-black precipitate has somewhat the color of the purple of Cassius, which is characteristic of colloidal gold.

In conclusion, it may be said with confidence that it is doubtful whether a pure preparation of aurous oxide has ever been prepared.

Summary

1. The potential of the gold-auric oxide electrode, Au (cryst.), Au₂O₃ (s), H⁺ has been found to be -1.362 volts.
2. The free energy of formation of auric oxide at 25° has been found to be +18,810 cal. from electromotive-force measurements.

LUMINESCENCE OF GRIGNARD COMPOUNDS IN ELECTRIC AND MAGNETIC FIELDS, AND RELATED ELECTRICAL PHENOMENA

BY R. T. DUFFORD, DOROTHY NIGHTINGALE AND L. W. GADDUM

RECEIVED SEPTEMBER 16, 1926

PUBLISHED AUGUST 5, 1927

Previous work by the authors and their colleagues¹ has shown the existence of interesting and remarkable regularities in the relations between chemical structure and the brightness and spectral distribution of the light emitted when ether solutions of Grignard compounds, having the general formula $RMgX$, are oxidized with air or oxygen. The behavior of this group of compounds raises many questions regarding the molecular structures involved.

It seemed possible that some light in this direction might be obtained from experiments with strong magnetic and electric fields. If the radiators are electrons in orbits, as current ideas go, it seemed barely possible that the application of a strong field might bring about a uniform orientation of the molecules, or of the orbits within the molecules, and that this condition might result in polarization of the light emitted in such a field.

The experiment was therefore made of oxidizing certain of the brighter compounds in magnetic fields of about 15,000 gauss; but in every case, polarization appeared to be completely lacking. If it existed, it could not have exceeded one or two per cent. However, one effect was clearly visible; in the strongest fields, there was a distinct tendency for the most of the emission to occur in the most intense parts of the field, near the pole pieces. Immediately on applying the field, a streaming appeared in the solution, with the brightening at the sides of the crucible containing the solution. It appeared as if the effect were mechanical, either the Grignard or, more probably, the oxidation product, being sufficiently paramagnetic to be drawn to the poles. If the solution were very clear to begin with, it would soon show minute black specks being drawn to the poles with the streams. Most of the oxidation product collected near the poles. The effect is shown well by $p\text{-BrC}_6\text{H}_4\text{MgBr}$. It does not, however, appear in weak fields.

¹ Dufford and co-workers, *THIS JOURNAL*, 47, 95 (1925); 45, 2058 (1923); 45, 278 (1923); *J. Optical Soc. Am.*, 9, 405 (1924); *Phys. Rev.*, 21, 203 (1923); 27, 247 (1926).

The similar study of these compounds in strong electric fields is impossible, because of the remarkably high conductivity of their solutions which are, indeed, quite comparable with aqueous solutions in showing the properties of electrolytes.² Tests were made with voltages up to 1500. The experiments at once brought out what appears to be a quite distinct type of luminescence, which occurs at one or both electrodes, and is not due to oxidation at the surface of the liquid. Usually the light appears at the anode but sometimes it is at the cathode, or at both electrodes. The effect is not always visible at low voltages. A surprising fact is that the brightness of the light appears to have little if anything to do with the brightness obtained on reaction with oxygen. In no case was any trace of polarization observed in the light. Table I gives a list of typical examples and it will be noted that some compounds that give no light on oxidation with oxygen show the effect, while the brightest of the oxy-luminescent substances hardly show the present effect at all.

TABLE I

LUMINESCENCE DURING ELECTROLYSIS OF GRIGNARD COMPOUNDS

Grignard compound from	Light during electrolysis	Remarks
Methyl iodide	None	
Ethyl iodide	None	
<i>n</i> -Butyl bromide	None	
<i>iso</i> -Amyl bromide	None	
<i>n</i> -Lauryl bromide	Faint	Seen only above 1000 v.
Trimethylene bromide	Faint	Seen only above 500 v.
Bromocyclohexane	Faint, momentary	Seen only above 1000 v.
Benzyl chloride	None	
β -Bromostyrene	Faint	Less than with oxygen
Phenyl bromide	Fair	About equal to light with O ₂ ; easily visible at 110 v.
Phenyl iodide	Faint	Visible with 110 v.
<i>p</i> -Iodotoluene	Fair	Stronger at 1500 v. than oxidation
<i>p</i> -Chloro-bromobenzene	Very faint	Much less than with O ₂ even at 1500 v.
<i>p</i> -Dibromobenzene	Faint	Less than with oxygen
1,2,4-Chloro-bromotoluene	Faint	Visible above about 500 v.
α -Bromonaphthalene	Very faint	
β -Bromonaphthalene	Faint	At cathode
1,4-Chloro-bromonaphthalene	Fair	At anode; appears between 500 and 600 v.
	Faint	At cathode; appears between 600 and 700 v.
β -Iodonaphthalene	None	

In a recent article, Evans and Diepenhorst³ have questioned the conclusion of the writers that luminescence on oxidation of a Grignard com-

² Nelson and Evans, *THIS JOURNAL*, 39, 82 (1917). Kondyrew, *Ber.*, 58, 459 (1925).

³ Evans and Diepenhorst, *THIS JOURNAL*, 48, 715 (1926).

pound with oxygen, in ethyl ether solution, appears only if the —MgX group is attached directly to an unsaturated carbon atom. They state that they have obtained light from several Grignard compounds made from derivatives of saturated hydrocarbons, but do not state what solvent was used or whether the light was obtained from the crystallized compounds. The writers have carefully re-examined every such compound mentioned by Evans and Diepenhorst, without finding light in any case. Evidently the conditions for obtaining light, if it is emitted by such compounds, were not the same as used by the writers, that is, combination with oxygen while dissolved in ethyl ether.

Regarding the brightness of these compounds, Evans and Diepenhorst state that the "luminescence is proportional to the molecular weight of the halogen derivative so long as a definite series is considered without change in the chemical nature of the group or—in the case of the aromatic compounds—in position." So far as aliphatic compounds are concerned, Evans and Diepenhorst themselves appear to disprove the statement, by tabulating lauryl bromide as fainter than *iso*-amyl bromide. In the entire absence of quantitative measurements of brightness, the statement that a *proportionality* exists seems hardly justified. In the case of the aromatic compounds, it is true that the brightness increases when aliphatic groups of increasing formula-weight are substituted in the benzene ring, but this is the only case in which the brightness has been clearly shown to increase with molecular weight. On the other hand, there are several series, probably just as fairly called chemically similar, in which the brightness decreases when the molecular weight increases. This is the case in marked degree with the series $\text{C}_6\text{H}_5\text{MgCl}$, $\text{C}_6\text{H}_5\text{MgBr}$, $\text{C}_6\text{H}_5\text{MgI}$, with the series *p*- $\text{ClC}_6\text{H}_4\text{MgCl}$, *p*- $\text{BrC}_6\text{H}_4\text{MgBr}$, *p*- $\text{IC}_6\text{H}_4\text{MgI}$, and the series *p*- $\text{ClC}_6\text{H}_4\text{MgBr}$, *p*- $\text{BrC}_6\text{H}_4\text{MgBr}$, *p*- $\text{IC}_6\text{H}_4\text{MgBr}$. Other similar series are known. Evans and Diepenhorst have criticized the writers for concluding that mass is not the controlling factor, and that its influence is small compared with effects connected with the chemical nature of the compounds; but in view of the fact that only one series of compounds behaves in the way demanded by the "proportionality" of Evans and Diepenhorst, while there are several series which do not, and many more compounds which do differ chemically (for example, $(\text{CH}_3)_2\text{NC}_6\text{H}_4\text{MgBr}$) and which, when compared in molecular weight, seem to vary in brightness without much regard to molecular weight, the present writers feel that the effect of mass, if any, has not been clearly demonstrated. The question is simply one of interpretation of results, for with all these aromatic compounds the observations of Evans and Diepenhorst appear to repeat closely those of the writers.

The same authors criticize the writers for not noticing that the positions of the bands in the spectra from the oxidation of *p*- $\text{ClC}_6\text{H}_4\text{MgBr}$ and *p*- $\text{BrC}_6\text{H}_4\text{MgBr}$ are identical. They admit, however, that the light in

the two cases differs in color. They attempt to explain the difference by saying that the light must be a mixture of fluorescence and chemiluminescence. The explanation is both untenable and unnecessary. In all known cases, the ratio between the intensities of fluorescent and of exciting light is so small that it is almost inconceivable that light as faint as chemiluminescence could produce perceptible fluorescence, and if it did, the spectra would show it, for the fluorescence spectra that would be observed are multiple-banded, and these bands do not appear on the photographs; they would be readily distinguishable if present. However, difference in color can mean only one thing—a difference in spectral distribution of energy; this is true no matter what the origin of the light may be. Now each of the chemiluminescence spectra shows a single, fairly symmetrical band, and the bands do not differ greatly in width. About the only possible difference would thus appear to be in the location of the maxima. Even a rough examination of the spectra, either in the articles by the writers or in those of Evans and Diepenhorst, will show that the maximum for $p\text{-BrC}_6\text{H}_4\text{MgBr}$ lies somewhat on the violet side of the helium line at $\lambda 4472$, while for $p\text{-ClC}_6\text{H}_4\text{MgBr}$ the maximum lies considerably on the long wave-length side of this line. The existence of such a difference was of course clearly indicated by the earlier work in which monochromatic filters were used.

The processes involved in the luminescence during electrolysis are probably different from those occurring during combination with oxygen. It is, therefore, not necessary to conclude that since one process gives luminescence, the other must also. The fact that the processes are different is shown by the following. It is found that while some Grignard compounds on electrolysis deposit magnesium immediately, others do not at first; the deposition potential of the magnesium varies for the different compounds, in some cases being high enough for other reactions to occur first. In such cases, it is often observed that a brown, oily liquid forms, which settles slowly. Some of this material seems to form in some cases even when magnesium is deposited. The liquid appears to be $\text{MgBr}_2 \cdot 2(\text{C}_2\text{H}_5)_2\text{O}$. This substance can be prepared by methods not involving the use of Grignard compounds. However it is prepared, it is found to have the property of emitting light on electrolysis, just as many of the Grignard compounds do. The light emitted is so similar in the two cases that it seems probable that in many instances, especially with the saturated compounds, the formation of this substance, or possibly other etherates, may explain the entire luminescent effect.

Incidentally, it is worth pointing out that the magnesium which is deposited by electrolysis of these compounds is in a highly active state; it can be used to obtain good yields of some compounds, as $\text{C}_6\text{H}_5\text{MgCl}$, that are not easy to make.

The fact that ether solutions of Grignard compounds are closely comparable in their electrolytic properties with aqueous solutions of inorganic substances, opens a wide field for investigation. Some progress has been made by the writers and their colleagues in three directions: the study of decomposition potentials, the study of the complicated processes occurring in the electrolysis of these compounds, and the study of electrode potentials. The present article, however, will present only some important preliminary results from the last of these fields, that have shown a most interesting effect which is a converse of the luminescence on electrolysis. It is hoped that further results may be presented in later papers.

If a pair of strips of dissimilar metals is carefully cleaned and immersed in a solution of a Grignard compound, the strips will be found to have different potentials; they are the electrodes of a cell, a battery. Of course the cell must be sealed to prevent oxidation of the solution. A number of such cells have been studied, using a potentiometer outfit capable of measuring e.m.f.'s to 0.00005 volt.

The e.m.f. of such a cell varies greatly, for three reasons: (1) the cells have high temperature coefficients; (2) they are strikingly sensitive to changes in the illumination they receive; (3) the e.m.f. may be a periodic function of the time, depending somewhat on the previous history of the cell. These facts make it extremely difficult to obtain results which are quantitative and reproducible and the following results are therefore regarded as only preliminary.

The luminescence, during electrolysis, having suggested the possibility of a converse effect, it did not take long to trace certain violent eccentricity in the behavior of the first such cell studied, to the flashing on and off of the thermostat lamp in the water-bath used for regulating the temperature of the cell. The cell was put in a light-proof box, in a liter beaker of water kept at $21^{\circ} \pm 0.1^{\circ}$. The mere opening of a shutter in the box, exposing the cell to the light from a 100-watt incandescent lamp a meter away, would instantly raise the voltage of the cell to several times its value in the dark. The incandescent lamp was kept running continuously. An experiment with colored water in the beaker indicated that red light was not the most effective, but the use of glass containers means that the effective light is either visible or near ultraviolet. Both aliphatic and aromatic Grignard cells show the effect.

Fig. 1 shows the effect of *continued* irradiation on a cell with gold and silver electrodes, in molal solution of phenylmagnesium bromide. The cell was kept in the dark until the e.m.f. was steady. On opening the window to the light from a mercury arc, a constant source, the e.m.f. is seen to rise suddenly, to oscillate about a final value, and finally to become steady after about four hours. As readings were made at short intervals, even one minute apart at the critical parts of the curve, the

effect is not the result of accidental variations of a few readings. The second irradiation shows the same effect less prominently; also the less sudden drop in voltage when the light was excluded. Succeeding irradiations produced smaller effects, as shown. The temperature was constant to 0.05° in these experiments.

Other similar cells have given various similar curves (a number of these were shown at the Tulsa meeting of the American Chemical Society), some having a much greater oscillation in the e.m.f., and some showing the oscillations damped more quickly, some less quickly, than the example

Fig. 1.

shown, but all showing the marked sensitivity to light. Similar oscillations were observed in deposition potentials taken with platinum electrodes. The work of Hedges⁴ and associates indicates that such periodic functions of time may frequently be found in electrolysis of aqueous solutions of metal salts. No general theory of this effect has been given.

Cells with lead and copper electrodes gave erratic results, probably due to reactions at the electrodes; on standing, an oily liquid drips from the electrodes, and the solution shows a qualitative test for copper. While the values of the e.m.f. are not reproducible, the sensitivity to light appears to be always present, and the curves showing voltage variation with time have the same general shape. Magnesium-zinc cells, also sensitive, give much more closely reproducible e.m.f.'s.

Using a flowing junction method, with a cell made up of $\text{Mg} \mid \text{MgBr}_2 \cdot 2(\text{C}_2\text{H}_5)_2\text{O}$ (Sat. sol.) $\mid \text{C}_2\text{H}_5\text{MgBr}$ (1.5 M) $\mid \text{Mg}$, e.m.f.'s are obtained

⁴ Hedges, *J. Chem. Soc.*, 127, 1013 (1925).

which are very steady and reproducible, readings checking repeatedly within one or two in the third significant figure. The cell used gave about 0.2 volt, but the numerical value is significant only in showing the order of magnitude of the effect measured, since the exact value of the concentration of the Grignard solution was not known.

Summary

1. It is shown that strong magnetic fields produce no polarization in the light from the oxy-luminescence of ether solutions of Grignard compounds, but may affect the brightness.

2. The application of electric fields often causes an unpolarized luminescence at one or both electrodes, accompanying the electrolysis of the solution. The process involved appears to be quite distinct from the oxy-luminescence.

3. Preliminary study of electrode potentials in cells containing ether solutions of Grignard compounds shows that the voltage of such cells is very sensitive to light and that, following a change in illumination, the voltage may be a periodic function of the time.

4. Using a flowing-junction method, closely reproducible voltages were observed.

A THERMODYNAMIC TREATMENT OF CERTAIN MAGNETIC EFFECTS. A PROPOSED METHOD OF PRODUCING TEMPERATURES CONSIDERABLY BELOW 1° ABSOLUTE

BY W. F. GIAUQUE

RECEIVED DECEMBER 14, 1926

PUBLISHED AUGUST 5, 1927

Some years ago the author's interest in cryogenic work led to a consideration of possible substitutes for the commonly used methods of producing low temperatures.

While a method of producing very low temperatures was devised, the lack of necessary facilities has caused a temporary delay in the actual experiment and it is desired to transmit the underlying ideas at this time.

The reversible transfer of heat from one temperature to another requires a working substance which is capable of undergoing an isothermal entropy change at the temperatures concerned.

From a practical standpoint, this entropy change must be considerable in view of the unavailability of those theoretically convenient, thermally non-conducting materials.

Compared to those of pressure, the effects ordinarily produced by obtainable electric and magnetic fields on the neutral states of matter are minute. However, a critical consideration indicated that while the latter

cannot compete with pressure in producing a change in entropy at ordinary temperatures, a magnetic field will produce large effects at very low temperatures.

The important point is that the magnetic effects are large when pressure is no longer practicable as a means of producing a further drop in temperature.*

Before considering the available experimental data which lead to this conclusion it will be desirable to collect or derive certain thermodynamic formulas. Where possible the nomenclature of Lewis and Randall will be adopted.¹

The second law of thermodynamics as applied to substances in magnetic fields is $\oint dI + T dS = dE + PdV$.² Keesom omitted the PdV term, which actually makes but small difference. $\oint dI$ = the magnetic work done on the substance; $T dS$ = temperature times entropy change = the heat added; dE = the increase in internal energy; PdV = the work done against an external pressure; I = the intensity of magnetization in excess of that which would be in the same space if unoccupied by matter; $\chi = I/\oint =$ the molal susceptibility.

Since the method commonly used in the determination of magnetic properties involves the maintenance, as nearly as possible, of a constant magnetic potential, and also since we believe that the transfer of material from one maintained potential to another is somewhat easier to visualize than is an integral potential effect, we shall adopt the former viewpoint.

It will be convenient to extend the definition of heat content from $II = E + PV$ to $II = E + PV - \oint I$. The $\oint I$ term is included for a reason entirely analogous to that leading to the inclusion of the PV term. This latter is convenient, due to the maintenance of constant pressure by the earth's atmosphere under ordinary conditions.

Then as usual we may write the free energy as $F = II - TS$, $dF = dII - T dS - S dT = V dP - I d\oint - S dT$. Thus, at constant T and P ,

* Since this paper was submitted for publication there has appeared in the *Annalen der Physik* 81, 1154 (1926) a paper by P. Debye, who has independently arrived at the idea of utilizing the magnetic properties of $Gd_2(SO_4)_3 \cdot 8H_2O$ for refrigeration. Although the author of the present paper has frequently discussed his proposed method with numerous colleagues since 1924, the idea was not otherwise announced until the April 9th 1926 meeting of the California Section of the American Chemical Society when Professor W. M. Latimer discussed this author's proposed use of $Gd_2(SO_4)_3 \cdot 8H_2O$ for obtaining temperatures considerably below 1°K. Since the conception of the idea, equipment for producing liquid hydrogen in the necessary amount has been constructed and placed in operation. A helium liquefaction cycle which should soon enable experimental verification is now in process of construction.

¹ Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923.

² Keesom, *Comm. Phys. Lab. Leiden*, Suppl. No. 32a; Keesom (with note by H. A. Lorentz), *ibid.*, Suppl. No. 32b.

$dF = -Id\mathfrak{H}$ and the work done by a mole of substance when it is reversibly drawn into a field $= -\Delta F = \int_1^{H_2} Id\mathfrak{H}$.

Experimentally,³ consider the material investigated to be in the form of a cylinder of sufficient length to extend from the uniform field between the pole pieces of a magnet, through the magnetic gradient to a position where the field is negligible. When the cylinder moves into the field the net result has been a transfer of material from $\mathfrak{H}_1 = 0$ to \mathfrak{H}_2 . The force times the distance necessary to move one mole into the field H_2 is equal to $-\Delta F$.

$(\partial\Delta F/\partial T)_{\mathfrak{H},P} = -\Delta S$, and $-T\Delta S$ is the heat given out during the isothermal magnetization.

When values of susceptibility are given, an alternative method is as follows: $TdS = dE + PdV - \mathfrak{H}dI = dII + Id\mathfrak{H} - VdP$, from which

$$(\partial S/\partial \mathfrak{H})_{P,T} = (\partial I/\partial T)_{P,\mathfrak{H}} = \mathfrak{H}(\partial \chi/\partial T)_{P,\mathfrak{H}} \text{ and } \Delta S = \int_{\mathfrak{H}_1}^{\mathfrak{H}_2} (\partial I/\partial T)_{P,\mathfrak{H}} d\mathfrak{H}.$$

Diamagnetism is practically independent of temperature and thus there is nearly zero heat effect when a diamagnetic substance is introduced into a field.

The ideal paramagnetic substance follows the well-known law $\chi T = C = \text{constant}$, proposed by Curie⁴ and first explained by Langevin.⁵

For such a substance, $\Delta S = -\mathfrak{H}^2 C/2T^2$ when it is taken from zero field to field \mathfrak{H} . The inverse square proportionality of temperature to ΔS leads to considerable effects at very low temperatures, as will be shown later. The above expression for ΔS would lead to infinite decrease in entropy during magnetization at the absolute zero, which conflicts with the accepted view of the finiteness of entropy.⁶ The explanation, as in other such cases, is furnished by quantum mechanics and the fact that Curie's law is a limiting case for $\mathfrak{H} = 0$.

The low-temperature experimental data⁷ on gadolinium sulfate, $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$, so satisfactorily illustrate the possibilities that they alone will be considered.

Table I gives the values of the Curie constant at various temperatures for one gram atom of gadolinium as the hydrated sulfate. The various experiments have been carried out on two different tubes of material known as Gd I and Gd II.

O. and P., Onnes and Perrier, W., Woltjer; O. and O., Onnes and Oosterhuis.

The perfection of the magnetic behavior is clearly demonstrated. The constancy during a given series of measurements exceeds the agreement between the various series by a considerable amount, thus indicating constant error in a given set. For example, it is pointed out by Woltjer that the Gd I tube was out of center during his measurements.

Fig. 1.

Measurements have also been carried out by Woltjer and Onnes^{7c} at various temperatures from 1.3°K. to 4.2°K. with continued perfect behavior except deviations due to approaching saturation. These latter measurements have been considered in some detail in the following paper. From them we have calculated by graphical integration the values of ΔF for magnetization. The temperature coefficient of ΔF gives ΔS for the process and $-T\Delta S$ the heat given out during isothermal magnetization. At 1.3°K. a field of 20,000 gauss produces a decrease in entropy of 3.3 cal. per degree per gram atom of gadolinium. The decrease for 15,000 gauss is 2.9 cal. per degree at the same temperature. The heat evolved

during magnetization by fields of 15,000 and 20,000 gauss is plotted against temperature in Fig. 1. While the amount of heat is small, the effects are actually large when the temperature at which they occur is considered. For purposes of comparison it may be noted that an entropy change of 3.3 cal. per degree at room temperature corresponds to about 1000 cal.

It is apparent that a Carnot cycle could be used to transfer heat from one temperature to another. However, we believe that the following somewhat simpler procedure would suffice to produce temperatures much lower than those produced by any present method. (1) Magnetization of the working substance while it is in thermal contact through gaseous conduction with liquid helium preferably boiling at reduced pressure. (2) Demagnetization after the space between the working substance and the liquid helium bath has been evacuated.

Dysprosium sulfate, $\text{Dy}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$, or some other "diluted" dysprosium or holmium compound would apparently be the best working substance obtainable, the reason for this being that measurements indicate that dysprosium and holmium have about 10/7 the magnetic moment possessed by gadolinium. The "dilution" of the magnetic atoms by means of non-magnetic atoms appears to be necessary if perfect magnetic behavior is to be expected. This question has been discussed by Onnes and Oosterhuis.⁸

It does not appear probable that $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ would have any considerable heat capacity in the region about 1°K., but no heat-capacity data are available to decide this point. We expect to investigate the heat capacity of substances of this type at very low temperatures in the near future.

The very reversible character of the process is indicated by the absence of hysteresis effects. Breit and Onnes⁹ have investigated the hysteresis of chromic chloride and $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ at the boiling point of hydrogen and very high frequencies, and while the susceptibility of both materials was apparently lowered they concluded that "The order of magnitude of the susceptibility is unchanged if the frequency is increased to 3.69×10^5 ." This indicates that the magnetons are in extremely rapid equilibrium with thermal energy.

The question as to why heat effects have not been observed by experimenters making magnetic measurements suggests itself. An amount of material containing only about 0.001 gram atom of gadolinium was used and this was in thermal contact with the bath by means of hydrogen or helium gas conduction. It would thus seem that the effect could hardly have been sufficient to be distinguished from those possible due to lack of ordinary thermal distribution in the powdered material.

⁸ Onnes and Oosterhuis, *Comm. Phys. Lab. Leiden*, No. 139c

⁹ Breit and Onnes, *ibid.*, No. 168c

Some Applications

Bohr Magnetron Number.—The very successful low temperature investigation of $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ was started by Kamerlingh Onnes with the idea of obtaining the approach to saturation and thus a direct determination of the magnetic moment. This was possible only because of the high magnetic moment of the gadolinium atom. It would now seem possible to extend this method to other less magnetic substances with the assistance of cooling by relatively larger amounts of a substance with high magnetic moment. As was first pointed out by Onnes in connection with cryogenic work of this kind, the intensity of magnetization being a function of M/T , our inability to obtain very large fields combined with the fact that values of the magnetic moment are small may be overcome by lowering the temperature.

Electrical and Thermal Conductivity.—The investigation of thermal and supraconductivity at still lower temperatures may throw light on certain underlying principles and mechanisms which are as yet somewhat obscure, to say the least. The heat flow for measuring thermal conductivity could conveniently be supplied by the field and a magnetic substance if properly controlled. Further study of the lowering of the temperature at which supraconductivity begins when a magnetic field is applied should prove profitable.

Calorimetry.—Woltjer and Onnes^{7c} have suggested the use of magnetic susceptibility for thermometric purposes. The following method of determining heat capacities at suitable temperatures would seem capable of development to a considerable degree of accuracy. (1) Isothermal magnetization of a working substance in thermal contact with a bath and the material to be investigated. (2) Adiabatic demagnetization of the working substance plus the material investigated to various final field strengths. (3) Measurement of the forces due to a small fraction of the paramagnetic material located in the magnetic gradient as a means of determining both initial and final temperatures.

The possibilities of this method will be more evident when the quantum treatment given to the effects concerned is considered. This will be found in the following paper. By such a method the question of zero-point entropy for supercooled liquids such as glycerol¹⁰ could be still further investigated.

The orientation of di-poles in an electric field presents an analogous phenomenon to that which we have been discussing, but the orientation of a di-pole would probably involve the turning of a molecule in a solid. While this turning is one which might take place through some small angle, especially where the crystal consists of simple molecule units, it

¹⁰ Gibson and Giauque, *THIS JOURNAL*, **45**, 93 (1923). Simon and Lange, *Z. Physik*, **38**, 227 (1926).

seems unlikely that such an effect would be accompanied by a sufficiently large entropy change to be useful for such purposes as those considered. However, there are few data on this point.

Summary

A thermodynamic treatment of certain magnetic phenomena has been given.

The entropy change accompanying the magnetization of paramagnetic substances and its application to obtaining temperatures below 1°K. has been discussed.

Some remarks have been made concerning the analogous case of di-pole orientation in an electric field.

Some suggestions have been made concerning the application of temperatures obtainable to the direct determination of the number of magnetons in paramagnetic substances, the further investigation of thermal and superconductivity, and a method suitable for the determination of heat capacities below 1°K.

PARAMAGNETISM AND THE THIRD LAW OF THERMODYNAMICS. INTERPRETATION OF THE LOW-TEMPERATURE MAGNETIC SUSCEPTIBILITY OF GADOLINIUM SULFATE

BY W. F. GIAUQUE

RECEIVED DECEMBER 14, 1926

PUBLISHED AUGUST 5, 1927

It is the primary purpose of this article to show that the ordinary method of obtaining an absolute value of the entropy of a substance by means of the third law of thermodynamics is not always applicable to paramagnetic substances. It is also desired to show how the present method may be extended to correct for the paramagnetism in such cases.

Before proceeding to do this it will be desirable to interpret the measurements of Woltjer and Onnes¹ on the magnetic properties of gadolinium sulfate, $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$, in order that this substance may be used as an example for discussion.

Onnes and Woltjer show that their data follow the equation of Langevin² but express some surprise at the magnitude of the deviations. However, they did not feel able to claim that the difference was beyond the error of experiment. A decidedly systematic trend is noticeable in their observed minus calculated differences.

According to Langevin, the molal intensity of magnetization $I = M / (\coth M\mu / RT - RT / M\mu)$, where M is the molal magnetic moment, μ

¹ Woltjer and Onnes, *Comm. Phys. Lab. Leiden*, No. 167c.

² Langevin, *Compt. rend.*, 140, 1171 (1905).

the magnetic field strength, R the molal gas constant and T the absolute temperature. It may readily be shown by methods given in the preceding article that for a Langevin substance the entropy change during magnetization from zero field to field H is

$$\Delta S = R \left[\ln \frac{\sinh \frac{MH}{RT}}{\frac{MH}{RT}} - \frac{MH}{RT} \coth \frac{MH}{RT} \right]_{H=0}^{H=H}$$

which indicates that the entropy decreases to negative infinity as the field is increased without limit. This is obviously due to the fact that Langevin assumed the existence of a continuous series of orientations with respect to the applied field.

Pauli³ has shown that the initial susceptibility of paramagnetic substances is best explained by the application of Langevin's method and the assumption of a small number of possible orientations. This latter can hardly be considered an assumption in view of the multiplicity observed in the Zeeman effect and the splitting of a stream of paramagnetic atoms passed through a magnetic gradient first observed by Gerlach and Stern.⁴

At the time Pauli first tested his proposal the anomalous Zeeman effect had not been sufficiently interpreted to enable the choice of the correct number of possible orientations in the various cases. However, the solution of this problem appears to be in a fairly satisfactory state at present.

Pauli's treatment of magnetic susceptibility has been for the limiting case as the field approaches zero, since at room temperature the values are independent of field strength within the limit of experimental error. However, at low temperatures this is no longer the case, and it will be necessary to derive the complete expression.

Hund⁵ has shown that for the trivalent gadolinium ion the inner quantum number j is $7/2$, while the ratio of magnetic over mechanical moment g is 2 in this case. When j is $7/2$, eight spatial orientations with respect to the field are possible,⁶ four of which have clockwise and four counterclockwise rotation. All eight of these situations are taken as equally probable in the absence of an external field.

The four angles of orientation for a gadolinium ion are given by $\cos \Theta = j/j, (j-1)/j, (j-2)/j, (j-3)/j$, respectively, where Θ is the angle between the plane of rotation and a plane normal to the field.

The magnetic moment is gjM , where M is now taken as the moment of a molal unit Bohr magneton.

The torque exerted by the field = $gjM \sin \Theta$.

³ Pauli, *Physik. Z.*, 21, 615 (1920).

⁴ Gerlach and Stern, *Z. Physik*, 9, 349 (1922).

⁵ Hund, *ibid.*, 33, 855 (1925).

⁶ Sommerfeld, "Atombau und Spektrallinien," Vieweg, Braunschweig, 1922, 4th ed., p. 616.

The work done by the field when the magnetic moment is turned from Position Θ to the completely lined up position in Field \mathfrak{H} is $gjM\mathfrak{H}(1 - \cos \Theta)$ for those with the field, $gjM\mathfrak{H}(1 + \cos \Theta)$ for those against the field.

Then $N = Z \Sigma e^{-\frac{gjM\mathfrak{H}(1 - \cos \Theta)}{RT}} + e^{-\frac{gjM\mathfrak{H}(1 + \cos \Theta)}{RT}}$ where N is Avogadro's number and Z is the number of atoms entirely lined up; and

$$I = (Z/N) \Sigma gjM \cos \Theta \left[e^{-\frac{gjM\mathfrak{H}(1 - \cos \Theta)}{RT}} - e^{-\frac{gjM\mathfrak{H}(1 + \cos \Theta)}{RT}} \right]$$

$$= gjM \frac{\Sigma \cos \Theta \sinh \frac{gjM\mathfrak{H} \cos \Theta}{RT}}{\Sigma \cosh \frac{gjM\mathfrak{H} \cos \Theta}{RT}} \quad (1)$$

both summations being over all possible orientations. The above formula is general for all cases where $2j$ is odd, and the orientation is without restraint when $\mathfrak{H} = 0$. When $2j$ is even, a similar treatment leads to

$$I = gjM \frac{\Sigma \cos \Theta \sinh \frac{gjM\mathfrak{H} \cos \Theta}{RT}}{\frac{1}{2} + \Sigma \cosh \frac{gjM\mathfrak{H} \cos \Theta}{RT}} \quad (2)$$

The value of the magnetic moment is given by the equation $M = (e/m)(h/4\pi)N$ where e/m is the ratio of electronic charge to mass in electromagnetic units, and h is Planck's constant. Birge,⁷ after careful consideration of the available data, has adopted as the most probable values of the constants involved $e/m = 1.760 \times 10^7$ e. m. u.; $h = 6.560 \times 10^{-27}$ erg sec.; $N = 6.059 \times 10^{23}$. Thus, $M = 5567$, and for the gadolinium ion the total magnetic moment $gjM = 2 \times (7/2) \times 5567 = 38,970$, which is saturation value of this substance.

It has been shown by numerous experiments that the initial susceptibility of the gadolinium ion is within the limits of experimental error equal to that of $\frac{1}{2}\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ when corrections have been applied for the associated diamagnetic effect. The available data on this point have been summarized by Zernike and James.⁸ It might be expected that the definite arrangement of the atoms in a crystal lattice would influence the magnetic properties, but this is apparently not the case with $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$.

11	3.40	1.852	.6341	35	1.31	6.266	.9403

The experimental data are compared with the theoretical curve in Fig. 1. The agreement is very satisfactory, particularly when it is considered that

Fig. 1.

the theoretical curve is calculated from natural constants whose values are in no way dependent on the work of Onnes and Woltjer.

The calculation of the theoretical value of the entropy of magnetization

may be carried out by a method used by Tolman and Badger⁹ to obtain the rotational entropy of diatomic gases.

Let $gjM\hbar/RT = a$ and $Q = \sum \cosh(a \cos \Theta)$. Then $dQ/da = \sum \cos \Theta \sinh(a \cos \Theta)$, and $I = gjM d \ln Q/da$. From the preceding paper, $(\partial S/\partial \hbar)_T = (\partial I/\partial T)_\hbar$. Therefore,

$$\begin{aligned} \left(\frac{\partial S}{\partial \hbar}\right)_T &= -\frac{a^2 R}{\hbar} \left(\frac{\partial^2 \ln Q}{\partial a^2}\right)_\hbar \\ \Delta S &= -R \int_0^\hbar \frac{a^2}{\hbar} \frac{\partial^2 \ln Q}{\partial a^2} d\hbar = R \left[\ln Q - a \frac{d \ln Q}{da} \right]_0^\hbar \\ &= R \left[\ln \sum \cosh \frac{gjM\hbar \cos \Theta}{RT} - \ln 4 - \frac{gjM\hbar}{RT} \frac{\sum \cos \Theta \sinh \frac{gjM\hbar \cos \Theta}{RT}}{\sum \cosh \frac{gjM\hbar \cos \Theta}{RT}} + 0 \right] \quad (3) \end{aligned}$$

The ΔS for various values of a has been calculated by means of Formula 3 and the results are tabulated in Table III. The limiting case for large values leads to $-R \ln 8$ as of course it must, since eight positions were assumed equally probable in zero field, while only one is possible for the case $a = \infty$. Thus, when 0.5 mole of $Gd_2(SO_4)_3 \cdot 8H_2O$ initially in zero field is completely saturated the entropy change is -4.14 cal. per degree. It may be noted that when $a = 7$, $\hbar = 19,420$ when $T = 1.3^\circ K$.

1.4	.664	6.3	3.066
2.1	1.196	7.0	3.223
2.8	1.674	∞	4.135

The use of a nearly perfect paramagnetic substance and Langevin's equation for thermometric purposes as suggested by Woltjer and Onnes¹ might be more accurately carried out if Equations 1 or 2 were substituted, depending on the character of the substance used.

Equation 3 might be used for calculation of the heat effect in the magnetic method of mixtures, proposed in the preceding article, for the measurement of heat capacities below $1^\circ K$.

A substance obeying Equation 1 would be a strong magnet if cooled to the absolute zero in any finite field. It is interesting to note that could the substance be taken to the absolute zero in the absence of any field the entropy change, if subsequent magnetization took place, would be finite. This is in some respects similar to the entropy change accompanying unmixing of the constituents of solutions, in this case the mixing (demagnetization) and unmixing (magnetization) being under the control of a field. However, if the atoms affected each other in a ferromagnetic sense the substance would become a saturated magnet even in the absence of a field.

⁹ Tolman and Badger, THIS JOURNAL, 45, 2277 (1923).

The low-temperature deviations of paramagnetic substances from Curie's law are seldom of a ferromagnetic nature. The formula $\chi(T + \Delta) = C^{10}$ represents a large share of the initial susceptibility data surprisingly well, the values of Δ being positive in most cases. This leads at low temperatures to a susceptibility which is nearly independent of temperature, making it seem probable that such substances would approach the absolute zero without appreciable magnetization.

We may take the case of solid oxygen as an example of a substance which, while remaining strongly paramagnetic, would not become a magnet as the absolute zero is approached, since it has been shown by Perrier and Onnes¹¹ that the initial susceptibility of the form stable at the temperatures of liquid hydrogen is practically without temperature coefficient.

As the third law of thermodynamics has been used, entropy is calculated by the integration of specific heat with respect to the natural logarithm of temperature plus what has seemed a plausible extrapolation beyond the lowest temperature measured. When the above method is used the entropy due to the distribution of magnetic moment in the various possible states will sometimes be included, but will more often be neglected.

In view of our limited knowledge concerning atomic structure the assignation of an absolute value to the entropy of a substance would seem to be a somewhat uncertain procedure. However, for the purposes of chemistry it will be sufficient if all effects which may be produced by chemical reactions are considered.

Lewis¹² has called attention to the importance of magneto-chemical effects and one may refer to his publications for a discussion of this subject. While reactions involving a change in magnetic moment are considerably in the minority they are by no means infrequent, for example, the reactions of oxygen. Lewis has suggested that strained conditions which may be an essential part of certain types of chemical bonds may lead to only partial balancing of magnetic moment. Many chemical as well as magnetic observations support this view. In such cases the definite positions of the constituent magnetons would lead to no randomness or entropy of the type here considered. This type of paramagnetism should be practically without temperature coefficient.

Ewing¹³ reconsidering his theory of ferromagnetism has discussed a very plausible explanation requiring in part random and in part fixed distribution of the magnetons in ferromagnetic substances. We presume that the fixed magnetons would be of the valence type although all electrons of the valence group may not be fixed.

¹⁰ Onnes and Oosterhuis, *Comm. Phys. Lab. Leiden*, No. 129b.

¹¹ Perrier and Onnes, *ibid.*, No. 139c.

¹² Lewis, "Valence and the Structure of Atoms and Molecules," Chemical Catalog Co., Inc., New York, 1923; *Chem. Rev.*, 1, 231 (1925).

¹³ Ewing, *Phil. Mag.*, 43, 493 (1922).

Langmuir¹⁴ mentions the possibility of interchange of electrons between the valence and kernel groups in the case of transition elements such as iron, cobalt and nickel. This seems to be consistent with both chemical and magnetic facts. This adds to the complication in these cases, especially if thermodynamic equilibrium exists between the various possibilities. This seems quite likely in some cases.

Parks and Kelley,¹⁵ in measuring the heat capacity of magnetite, Fe_3O_4 , have found a marked heat absorption in the region about 113–117°K., which they attribute to some magnetic change. It would thus be unsafe to correct for the magneton entropy on the basis of data obtained at ordinary temperatures without investigating the nature of this change. Millar, in an unpublished investigation on the same substance, has found that the heat absorption extends over a range of at least 20°.

The systems which we have been discussing are typical of those which the spectroscopist classes as degenerate, but which can be made undegenerate by the application of a magnetic, electric or gravitational field, as the case may be. It will be recalled that the adiabatic hypothesis of Ehrenfest¹⁶ or, as it has been called by Bohr, the principle of mechanical transformability, does not necessarily hold for degenerate systems. The existence of the earth's magnetic, electric and gravitational fields will presumably keep the various degrees of freedom concerned undegenerate for ideal systems. Assuming the ideal case to hold for actual systems, thus making $S = \int_0^1 C \, d \ln T$, where C represents the heat capacity, the practical difficulty still remains that the thermal effects associated with magnetic saturation by the earth's field, for example, would occur principally below 1×10^{-5} °K. This makes a knowledge of the magnetic properties necessary in order to consider the contribution to the entropy due to unbalanced magnetic moment.

Lewis and Gibson¹⁷ have stated that the entropy of perfect crystalline substances approaches zero at the absolute zero of temperature. A crystalline substance with random distribution of magnetic moment could not be considered perfect even though the effect on the atomic centers is practically negligible. Thus, our conclusions are in accord with those of the above authors.

We have discussed the data of $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ in order to add to the reality of our statements, but in the reactions of gadolinium during which it remains trivalent it is obvious that the entropy due to magnetic moment would cancel.

¹⁶ Ref. 6.

¹⁷ Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923.

In the general case the amount of entropy $R \ln (1 + 2j)$ should be added to the entropy due to other causes; j is the number of units of resultant angular mechanical momentum of the unit which can be oriented. It is the mechanical rather than the magnetic moment which determines the number of possible positions. At the present time we believe there are no equilibrium, heat-capacity and magnetic data of sufficient completeness and accuracy to serve as a test of the above statement. The amount is 1.38 cal. per degree for one-half and 2.18 cal. per degree for one unit of resultant angular momentum.

Summary

The low-temperature magnetic susceptibility data of gadolinium sulfate, $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$, have been shown to agree quantitatively with an equation, using natural constants and based on orientation without restraint within the solid.

The theoretical entropy changes accompanying the application of a magnetic field are considered.

It is suggested that the magnetic formulas proposed be used in connection with Woltjer and Onnes' suggestion of paramagnetic thermometry. It is also suggested that they be used in connection with the magnetic mixture method of low temperature calorimetry as previously suggested by this author.

Assuming that the entropy of a perfect crystalline substance is zero at the absolute zero of temperature, it is shown that it is not always feasible to obtain an absolute value of entropy from heat-capacity data alone in the case of substances with a positive susceptibility.

It is shown how to correct for the above deficiency when the number of units of unbalanced mechanical moment is known from magnetic data on the form of the substance existing at temperatures low enough to permit sufficiently accurate extrapolation of the heat-capacity curve resulting from ordinary thermal effects.

SODIUM MONOMETAPHOSPHATE AND ITS ACID HYDRATION

BY H. T. BEANS AND SAMUEL J. KIEHL

RECEIVED DECEMBER 23, 1926

PUBLISHED AUGUST 5, 1927

The hydration of metaphosphoric acid to orthophosphoric acid or a metaphosphate to the orthophosphate, as $\text{NaPO}_3 + \text{H}_2\text{O} \rightleftharpoons \text{NaH}_2\text{PO}_4$, has attracted the attention of chemists ever since the epochal work of Graham.¹ Much work has been done but the problem is not completely solved. Graham was aware of some of the difficulties to be encountered. In his work he states, "The problem is, therefore, environed with difficulties." These difficulties are twofold. First, metaphosphoric acids or their salts are not well understood. It is thought that polymers exist, the preparation of which has not been thoroughly investigated, and the decision as to their forms has been based mainly upon their methods of preparation or empirical formulas rather than upon experimental evidence. Second, the rate of hydration must be ascertained by the measurement, at intervals, of either the concentration of the metaphosphate left unchanged in the solution or the concentration of the orthophosphate formed during the progress of the reaction. On account of the widely differing solubilities of the so-called polymeric forms of the metaphosphates, the direct determination involving an actual separation of the ortho- from the metaphosphoric acid is by no means easy. This separation is actually necessary in order to study the factors influencing the hydration.

In order to understand this reaction better the two above-mentioned difficulties must be overcome as far as possible. This requires, as a basic consideration, that a salt of well-established identity be prepared and its hydration studied. Furthermore, the definite salt must be readily and quantitatively separable from the substances formed during the hydration.

Heretofore the methods employed in the study of the hydration of metaphosphoric acid have been to a great extent indirect, and the acid used was prepared by dissolving phosphorus pentoxide in cold water, by dehydrating orthophosphoric acid or by preparing a heavy metal salt from which a solution of the metaphosphoric acid was obtained by precipitating the metal with hydrogen sulfide. Acidimetry was used by Sabatier,² Montemartini and Egidi,³ Berthelot and André⁴ and Balareff;⁵ thermochemistry by Giran,⁶ gravimetric analysis by Holt and Meyers;⁷

change of index of refraction by Blake and Blake;⁸ change of conductivity by Prideaux;⁹ and change of the lowering of the freezing point by Holt and Meyers.¹⁰

In their gravimetric method Holt and Meyers precipitated the unchanged meta- in the presence of ortho- and pyrophosphates as a barium metaphosphate bearing the empirical formula $\text{Ba}(\text{PO}_3)_2$. By repeated experiments with mixtures of ortho-, pyro- and metaphosphates, they claim very little variation in the composition of their precipitate. Judging from the irregularity of the curve they publish it seems that their method is open to question or fraught with a considerable error.

Other attempts to apply methods of precipitation were employed to show whether or not pyrophosphoric acid was formed during the process of hydration.¹¹ These methods are not applicable to the problem, for on the one hand, the method of Berthelot and André requires the heating of the solution to be analyzed, acidified with acetic acid, on a boiling water bath for three or four hours to secure the formation of an uncertain magnesium ammonium pyrophosphate, a treatment entirely out of the question in view of the marked effects of temperature and hydrogen ion upon the rate of hydration; on the other hand, the precipitation of pyrophosphate of copper or cadmium in an acetic acid solution, the method employed by Balareff, is not free from doubt because upon it he based his contention that no pyrophosphate as an intermediate product was formed during the hydration, a statement not in harmony with his later work.¹²

Moreover, there have been two different opinions as to whether pyrophosphoric acid was formed as an intermediate product during the hydration of meta- to orthophosphoric acid. One group of chemists maintained that the hydration was direct to ortho-, while another claimed pyrophosphoric acid as an intermediate product. The former was supported by Graham,¹ Sabatier,¹³ Montemartini and Igidi³ and Balareff,¹⁴ while Berthelot and André,¹⁵ Giran,¹⁶ Holt and Meyers,¹⁰ and Balareff¹² adhered to the latter.

Accordingly, a method has been devised and materials prepared for the attack of this problem whereby the conditions and factors influencing the reaction may be studied to a better advantage by direct, standard analytical methods. An account of the investigation follows.

Apparatus

The apparatus used to measure the concentration of hydrogen ion has been described by Hansen and one of us.¹⁷

Preparation of Materials

Monosodium Phosphate, $\text{NaH}_2\text{PO}_4 \cdot 2\text{H}_2\text{O}$.—A quantity of the purest monosodium phosphate obtainable was crystallized thrice from distilled water. The precipitation was accomplished each time by adding to the aqueous solution an equal volume of redistilled 95% alcohol and cooling in ice water. The final product was obtained quite free from moisture by washing by suction on a Büchner funnel thrice each with absolute alcohol and absolute ether. To remove the ether it was exposed to the air for a short time on a clean surface. The dihydrate was thus obtained. Its high dissociation pressure prevented other methods of drying and required hermetically sealed bottles as containers.

The following analyses were made for water of hydration:

Lot	Sample	Water of hydration plus water of constitution, %
1	1	34.47
1	2	34.52
2	1	34.73

The theoretical percentage for the hydrate $\text{NaH}_2\text{PO}_4 \cdot 2\text{H}_2\text{O}$ is 34.63.

Sodium Monometaphosphate, NaPO_3 .—Sodium monometaphosphate was prepared by dehydrating the $\text{NaH}_2\text{PO}_4 \cdot 2\text{H}_2\text{O}$ as above prepared in a calibrated electric furnace. The hydrate in a large platinum crucible was held at a temperature of 200° for an hour. The temperature was then slowly raised during the next hour till the mass melted to a clear liquid. It was held at this temperature—approximately 600° —for ten minutes. Finally, the temperature was lowered to 450° and maintained at this point for two hours while the substance crystallized. At the end of this crystallization the metaphosphate was quickly cooled by dipping the bottom of the crucible in cold water.

The sodium metaphosphate above prepared was investigated by the freezing-point method with the following results.

Sodium metaphosphate, g.	Water, g.	F. p. depression	Mol. wt.
5.0472	100	0.916	102.5
2.8159	100	.546	95.9
1.3435	100	.351	86.9

These depressions indicate a sodium metaphosphate whose molecular weight corresponds to the formula NaPO_3 (Theoretical—102.04). The above sodium monometaphosphate was formerly prepared in a somewhat similar way¹⁸ from sodium ammonium hydrogen phosphate by heating the resulting vitreous mass from fusion till it crystallized or by slow cooling from fusion. By taking 2.77 g. of their crystals in 100 cc. of water, Holt and Meyers obtained a depression of $.51^\circ$, which corresponds to a molecular weight of 102 and a formula of NaPO_3 .

An optical study of the sodium monometaphosphate made by Professor R. J. Colony of the Department of Geology of Columbia University confirms our belief that the sodium monometaphosphate prepared above is

¹⁷ Kiehl and Hansen, *THIS JOURNAL*, **48**, 2802 (1926).

¹⁸ Tanatar, *J. Russ. Phys.-Chem. Soc.*, **30**, 99 (1898); Ref. 10 (b), p. 535.

a distinct chemical individual. Through the kindness of Professor Colony we are permitted to publish the following optical properties: "It has an index of refraction: $N_g = 1.486 \pm 0.005$, $N_p = 1.473 \pm 0.005$, birefringence $N_g - N_p = 0.013 \pm 0.005$. It is apparently monoclinic, optically negative and biaxial with a large optical angle. It shows uniformity in behavior, form and composition."

Sodium monometaphosphate is soluble in water. It reacts acid to litmus—a property described by Graham,¹ the explanation for which is not apparent. From a 0.3 *M* solution white, flocculent precipitates, which change to crystalline form on standing, may be obtained from solutions of the nitrates of silver, lead, mercury and bismuth. With solutions of the nitrates of zinc, cadmium, cobalt, nickel and copper, white amorphous precipitates are formed. It does not give a precipitate in a solution containing magnesium chloride, ammonium chloride and ammonium hydroxide in moderately high concentrations. This property was employed in the separation of monometaphosphoric acid from orthophosphoric acid.

Other Chemicals.—The hydrochloric acid, potassium chloride and mercurous chloride used were prepared according to the description given by Hansen and one of us.¹⁷

Method of Procedure

In planning a method of procedure the factors influencing the reaction have as far as possible been either measured or controlled. The temperature, the concentration of sodium monometaphosphate, the concentration of orthophosphate, the possible formation of pyrophosphate and the concentration of hydrogen ion are the variable factors which influence the hydration of sodium monometaphosphate.

The temperature was regulated and controlled at $45^\circ \pm 0.01^\circ$. The ortho- was separated from the metaphosphoric acid and determined directly. By difference the unchanged meta- was obtained. No satisfactory quantitative method has as yet been found whereby pyrophosphoric acid may be determined in mixtures such as occur in this investigation. Therefore, an estimate by other means of the amount formed is all that is possible. The concentration of hydrogen ion was measured at intervals during the hydration.

Preparation of Solutions.—All solutions were prepared at 20° . The requisite amount of sodium monometaphosphate was dissolved in water in a volumetric flask. To this was added with constant rotation to avoid local excess the amount of hydrochloric acid necessary to furnish the desired hydrogen-ion concentration. The solution was then diluted to volume as quickly as possible. After thorough mixing, the solution was put in a "non-sol" bottle and placed in the bath. The whole operation, beginning with the addition of the acid, required not more than ten minutes.

The specific gravity of each solution was taken at 20° by means of a Westphal

balance at the beginning of the reaction and again at the end. No change of volume was observed during the hydration greater than one part in one thousand. Hence one specific gravity measurement for each solution sufficed for calculating the amount of metaphosphate transformed to orthophosphate. The concentrations of the solutions were all expressed in moles per liter. Therefore, knowing the specific gravity and the concentration, the amount of sodium monometaphosphate in any weighed quantity of solution could be determined.

The Separation of Monometaphosphoric Acid from Orthophosphoric Acid.—Orthophosphoric acid was separated from monometaphosphoric acid by means of "magnesia mixture" in a cold solution. As previously stated, a solution of sodium monometaphosphate does not give a precipitate with "magnesia mixture" in concentrations used in this procedure—and in fact very much higher concentrations. This method of separation has been tested both qualitatively and quantitatively. Seventenths of a gram of sodium monometaphosphate together with 25 cc. of standard "magnesia mixture" in a total volume of 125 cc. was allowed to stand for 24 hours repeatedly and no precipitate appeared, while a precipitate of the orthophosphate appeared immediately in another solution similarly treated, excepting that 1 mg. of phosphorus in the form of orthophosphate was added. It remains now to be shown that monometaphosphoric acid is quantitatively separable from the orthophosphoric acid and that no appreciable hydration occurs during the time of standing required for the precipitation of the magnesium ammonium phosphate. Thirty determinations of orthophosphate according to the method outlined below, in the presence of varying quantities of sodium monometaphosphate from 900 mg. to 100 mg., have been made. The amount of orthophosphate used has varied and the times of standing have been 6, 12 and 18 hours, respectively. There was an increase in amount found over the amount added which was of the same order irrespective of the time of standing. This shows that hydration was not the cause of the increase; for if it had been, the amount of increase would have been a direct function of the time. This increase not due to hydration was inherent in the method and doubtless caused by adsorption and subsequent hydration by the acid used to dissolve the precipitate. The magnitude of the error from this source was found by the above determinations to be on the average not greater than ten parts per thousand for amounts of sodium monometaphosphate not exceeding 300 mg.

Determination of Orthophosphate.—Orthophosphate was determined by the standard gravimetric method. The samples of the solution were taken by means of Bailey weighing burets. Before precipitation each sample was diluted to 100 cc. Twenty-five cc. of "magnesia mixture" was then added, which made the final volume 125 cc. The separation of the magnesium ammonium phosphate precipitate from the unprecipitated meta- was made by filtration not more than 16 hours nor less than 6 hours after the first precipitation. After separating and washing with an ammonium hydroxide-ammonium nitrate solution, the orthophosphate precipitate was dissolved with hot hydrochloric acid and reprecipitated. Finally, after 12 hours' standing, the magnesium ammonium phosphate was filtered through a weighed Gooch crucible and weighed as magnesium pyrophosphate. By this method the amount of the monometaphosphate transformed to ortho- could be determined.

In the hydrations where the concentration of acid was high, the analytical results varied somewhat at the beginning of each hydration. The variation was due to the simultaneous precipitation of a gelatinous substance which contaminated the magnesium ammonium phosphate. This gelatinous precipitate was soluble in an excess of magnesium salts and from its behavior indicated that it was magnesium pyrophosphate. The pyrophosphate was formed during the hydration. The concentration

of hydrogen ion showing abnormally low values for the high acid concentrations indicated further that pyrophosphate was probably formed. With no satisfactory quantitative method for separating pyro- from orthophosphate and determining it, the difficulty was met by preventing its precipitation by the addition of an excess of "magnesia mixture" a method which was on the whole quite successful.

Measurement of Concentration of Hydrogen Ion.—All hydrogen-ion concentration measurements were made at 45° by the apparatus and method described by Hansen and one of us.¹⁷ The calculations were made by use of the formula $\log C_{H^+} = (0.2342 - E)/0.063$.

Experimental Data

The following table gives the concentrations and the densities of the solutions selected for investigation.

TABLE I

	D	E	H	K	O	Z	S
Molar concn., NaPO ₃	0.500	0.500	0.500	0.300	0.100	0.300	0.300
Molar concn., HCl.....	.483	.339	.192	.339	.339	.010	.000
d ₂₀ /d ₂₀	1.044	1.042	1.041	1.025	1.011	1.025	1.025

All hydrations except the Z and S were made in duplicate. Duplicate samples of the two exceptions were taken. The mean deviation of the results in duplicate is not greater than five per cent. when the concentration of pyrophosphate is high at the beginning nor greater than one per cent. when the hydration nears completion.

Discussion

The Change of Concentration of Hydrogen Ion.—The data in the foregoing tables and the curves in the accompanying figures given as example show that there was a considerable decrease in the concentration of hy

drogen ion in all cases when hydrochloric acid was added to the solution in the beginning. This decrease was progressive and became less pronounced as the transformation of the meta- to orthophosphate becan

Fig. 2.—Hydration and hydrogen-ion concentration curves of solution Z, 0.300 M NaPO_3 , 0.010 M HCl.

more nearly completed. The explanation is obvious. Monometaphosphoric acid is a stronger acid than orthophosphoric acid. When, howev

there was no acid added to the solution, as in solution S, an actual increase in the concentration of hydrogen ion occurred. This increase was due to the formation of hydrogen ions during the reaction to pyrophosphate and orthophosphate in a region where the concentration of hydrogen was below that given by the solution of the end-product, monosodium orthophosphate.

Abnormal Decrease of Hydrogen Ions in the First Part of Hydration.

In Figs. 1, 2, and 3, all the hydration curves show periods at the beginning where apparently very little orthophosphate was present in the solutions.

There was, however, at this point a reaction of a very pronounced character taking place. The hydrogen-ion concentration decreased more rapidly at this stage than at any other stage of its course. The change of hydrogen-ion concentration could not be explained by the very little orthophosphate which was undoubtedly present but not determinable. Even after the orthophosphate had acquired a comparatively high concentration it was insufficient to cause the change in concentration which occurred. For example, in Curve H, Fig. 1, there was a decrease of 0.14 mole of hydrogen ion when 0.10 mole of orthophosphate had been formed; in E, 0.13 mole, with the formation of 0.10 mole of orthophosphate; and in C, 0.16 mole of hydrogen ion disappeared when 0.10 mole of orthophosphate had been formed.

Furthermore, in studying these hydrations it was thought, at first, that the orthophosphate was produced directly from the metaphosphate. We therefore plotted the hydrogen-ion concentrations found against the orthophosphate concentration. These curves were compared with curves secured from the measurement of synthetic solutions of monosodium orthophosphate and hydrochloric acid in concentrations calculated to be identical with the experimental solutions, assuming that the orthophosphate was produced directly from the metaphosphate. It was thought proper to

omit the metaphosphate from these synthetic solutions since its effect on the hydrogen-ion concentration was slight. The curves in Fig. 4 represent the results from solutions D, E and H. Fig. 5 represents values from the corresponding synthetic solutions just described. When Fig. 5 is superimposed on Fig. 4 the result is shown in Fig. 6. The curves are not coincident. The hydrogen-ion values from the actual hydrations near the beginning are much lower than those from the seemingly comparable synthetic solutions. The differences, however, decrease as the reactions proceed, until finally, near completion, the concentrations of hydrogen ion in both cases become identical.

From the above consideration it is evident that synthetic solutions are

not entirely comparable to the solutions produced by hydrations. The actual solutions produced under conditions of hydration have a substance capable of diminishing the concentration of hydrogen ion beyond that which would be present if orthophosphate alone were formed. Therefore, inasmuch as pyrophosphate was detected during the analysis of samples and inasmuch as there was a decrease of hydrogen-ion concentration in

hydrochloric acid solutions when pyrophosphate is added, it seemed reasonably certain that the large decrease of hydrogen-ion concentration at the beginning was due to the pyrophosphate formed. During the reaction, however, it finally was hydrated to orthophosphate in the acid solution, thus tending to eliminate the difference of corresponding hydrogen-ion concentration values as the reaction approached more nearly complete transformation to orthophosphate.

In the hydration of solution S, where no acid was added, there was a

further indication of the formation of pyrophosphate. The concentration of hydrogen ion constantly increased. At the end of 200 days its value was 4.06×10^{-5} , while the concentration of 0.3 M monosodium phosphate, the natural end-product, gave a value of 3.81×10^{-5} . Then, too, the reaction was but 50 per cent. complete, with the hydrogen-ion concentration still showing a marked tendency to increase when judged

from the slope of its curve in Fig. 3. The final value it could ultimately attain would be about $1.5 \times 10^{-4}\text{ M}$, the value for a 0.15 M disodium dihydrogen pyrophosphate solution with no orthophosphate present. This concentration, moreover, could not be reached as orthophosphate was present. But the final value with no pyrophosphate present at complete transformation would be that for 0.300 M orthophosphate. Hence, a maximum in the hydrogen-ion concentration should be expected before complete hydration.

Comparison of Effects of Changes in Concentrations.—The results of the various hydrations indicate the comparative effects of the concentrations of metaphosphate and hydrochloric acid. The times required for the attainment of the same percentage transformation depended more upon the concentration of hydrogen ion in solution than upon the metaphosphate concentration. The data in Tables II, III, IV, V and VI, exemplified in Figs. 1, 2 and 3, confirm this assertion. Where the concentration of metaphosphate in solutions C, E and H initially was 0.500 *M*, with the hydrochloric acid 0.483 *M*, 0.339 *M* and 0.192 *M*, respectively, the times for the attainment of the same percentage hydration increased greatly with decrease of hydrogen-ion concentration. Likewise in solutions E, K and O, of 0.339 *M* hydrochloric acid and 0.500 *M*, 0.300 *M* and 0.100 *M* sodium metaphosphate, respectively, the concentration of hydrogen ion rather than the concentration of sodium monometaphosphate affects the rate of the reaction to the greatest extent. The influence of the concentration of hydrogen ion is most strikingly shown in solutions K, Z and S, of 0.300 *M* monometaphosphate with 0.339 *M*, 0.010 *M* and 0.000 *M* hydrochloric acid, respectively.

Summary

1. $\text{NaH}_2\text{PO}_4 \cdot 2\text{H}_2\text{O}$ was prepared, a hydrate not hitherto described.
2. Sodium monometaphosphate was prepared and its hydration studied by direct methods.
3. The hydrogen-ion concentration decreased as the reaction proceeded in regions of initial concentration above that given by the end-product, monosodium orthophosphate, but increased when the initial hydrogen-ion concentration was below that of the end-product.
4. Pyrophosphate was formed as an intermediate product. Its presence was detected during the separation and determination of orthophosphate. The abnormally low values for the hydrogen-ion concentrations at the beginning with high hydrochloric acid concentrations and the increasing of the hydrogen-ion concentration above that of the final end-product indicated that an acid stronger than orthophosphoric but weaker than hydrochloric was formed.
5. The hydration was much more affected by a change of concentration of hydrogen ions than by a change of the concentration of sodium monometaphosphate.
6. The presence of an intermediate product makes the reaction somewhat complex.

THE COMPRESSIBILITY OF TELLURIUM

BY ROBERT FRANKLIN MEHL¹ AND BEVERIDGE JAMES MAIR

RECEIVED MARCH 28, 1927

PUBLISHED AUGUST 5, 1927

Although the cubic compressibilities of a large number of elements have been determined in the Harvard Chemical Laboratories during the last twenty-five years by Richards and his collaborators,² thus far tellurium has escaped attention.

Four years ago P. W. Bridgman, in the Jefferson Physical Laboratory, determined the linear compressibility of a single crystal of tellurium³ and discovered the surprising fact that an increase in hydrostatic pressure caused an increase in length along the axis under observation. In a later paper⁴ Bridgman redetermined this coefficient on a casting in which the axis measured corresponded closely to the trigonal axis, and also determined the linear compressibility coefficient perpendicular to this axis. These two values for initial linear compressibility at 30° are, respectively, -0.4137×10^{-6} and $+2.748 \times 10^{-6}$, leading to a positive value for the initial cubic compressibility at 30° of 5.082×10^{-6} , pressures always given in kg./cm.². Bridgman pointed out in this second paper that the value found for the initial cubic compressibility does not fall on the periodic compressibility curve of Richards⁵ when atomic weights are used, but does fall on a smooth curve through the values for the neighboring elements when atomic numbers are used.

In order to study further the remarkable behavior of this element it was thought advisable to make a direct determination of the cubic compressibility.⁶ A negative coefficient of cubic compressibility is of course contrary to ordinary ideas of pressure and its effects and indeed to the principle of Le Chatelier, but the case of a negative coefficient of linear compressibility is somewhat less clear. It will be shown that this negative coefficient is completely orthodox. The compressibility of tellurium, however, is interesting from another point of view. With iodine it constitutes one of the three pairs of elements showing a reversed order in the periodic table from that of the atomic weights. These exceptional

⁴ Bridgman, *ibid.*, **60**, 370 (1925).

⁵ Richards and others, *Carnegie Inst. Wash. Pub.*, **76**, 66 (1907).

⁶ Bridgman's second paper came to the authors' attention after the work reported here had been completed, and while there is overlapping to a small extent the point of view of the present paper is thought to be sufficiently distinct to merit a separate statement.

elements should serve to emphasize the dependence of compressibility upon the extra-nuclear electronic structure of the atom, that is, the compressibility values of the elements in these pairs should fall on a smoothly sloping curve through the values of the neighboring elements when plotted according to atomic numbers but not when plotted according to atomic weights. One of the remaining pairs, argon and potassium, is useless for the purpose since argon is a gas, and the other, nickel and cobalt, is of little use because the compressibilities of these two elements are nearly identical,⁷ falling upon a flat portion of the periodic curve of Richards. Tellurium, however, should fall upon a steeply rising portion of the curve, since tin and antimony on its left have coefficients of 1.9×10^{-6} and 2.4×10^{-6} , respectively, and iodine and cesium on its right (when atomic numbers are used) have coefficients of 13.0×10^{-6} and 61×10^{-6} (xenon, a gas, is of course omitted).⁸

Method

The methods used to determine the compressibility coefficient of tellurium and to standardize the piezometer with which the measurements were made have been described elsewhere in considerable detail⁹ and will not be given here. The measurements were made at 25° instead of the usual 20°, however, and it was necessary to determine a new correction factor for water to apply at this higher temperature.¹⁰ This factor could, of course, be calculated¹¹ but it was thought better to determine it directly, especially since a direct determination would provide a dependable value for the compressibility of water at 25°, a datum not hitherto available.¹²

The greatest difference between the amounts of water used in the de-

⁷ Bridgman, *Proc. Am. Acad. Arts Sci.*, **58**, 5 (1923), found the compressibility coefficient of nickel to be 0.529×10^{-6} and that of cobalt 0.539×10^{-6} , both at 30°.

⁸ Richards, *This Journal*, **37**, 1643 (1915).

⁹ Richards, *J. Franklin Inst.*, **198**, 25 (1924); also Richards and Saerens, *This Journal*, **46**, 935 (1924).

¹⁰ Richards and Sameshima, *This Journal*, **42**, 49 (1920), used 0.2069 as the factor to be applied at 25°. This factor presumably was calculated from approximated values for the compressibility of water and that of mercury at 25°. The approximate nature of the factor used has no bearing upon the accuracy of the results obtained, since the amount of water used in each determination was nearly equal to that used in the standardization, so that the inaccuracy in the correction factor, appearing in the third decimal place, does not appear in the compressibility coefficients calculated. The compressibility coefficient for mercury at 25° used in the present work, namely, 4.00×10^{-6} , was taken from this previous paper.

¹¹ Richards, *Carnegie Inst. Wash. Pub.*, **76**, 33, 36 (1907).

¹² Amagat, *Ann. chim. phys.*, [6] **29**, 68, 505 (1893), determined the compressibility of water at 20° and 30° in intervals of 100 atm. between 100 and 500 atm. (and beyond). From these data an approximate value may be obtained for the average compressibility between 100 and 500 megabars and at 25°, namely, 41.9×10^{-6} . The value here determined directly is lower, and accurate to an additional decimal place.

terminations upon tellurium and that used in the standardization of the piezometer was 2.9993 g. A quantity of water roughly ten times as great was used for the determination of the water correction factor, in order to obtain a value sufficiently exact for the purpose without making a large number of determinations. Two experiments were carried out, yielding four values. These are given in Table I, together with the standardization factors of the piezometer used.

TABLE I

STANDARDIZATION OF PIEZOMETER

Wt. of water, 2.7928 g.

Wt. of mercury, 100-500 megabars.

0.7973 } .7966 } .7981 } .7985 }	0.8003 } .7931 } .7942 } .7908 }
.7938 } .8008 }	Average 0.7964 g. ^a

DETERMINATION OF WATER FACTOR

	Expt. No. 1	Expt. No. 2
Total wt. of water taken	26.8316 g.	27.1450 g.
Total wts. of mercury, 100-500 megabars.....	5.712 } 5.720 } g.	5.764 } 5.780 } g.
Wt. of mercury, 100-500 megabars, in excess of that used in standardization.....	4.916 } 4.924 } g.	4.968 } 4.984 } g.
Wt. of water in excess of that used in standardization.....	24.0388 g.	24.3522 g.
Water factor: wt. of mercury, 100-500 megabars per 1 g. of water.....	$\frac{4.916}{24.039} = 0.2045$ $\frac{4.924}{24.039} = 0.2048$	$\frac{4.918}{24.352} = 0.2040$ $\frac{4.984}{24.352} = 0.2044$
	Average: 0.2044	

^a These values refer to a common quantity of water, namely, 2.7928 g., and have been found by converting the original values to this basis by applying the water correction factor for the difference. The bracketed values represent the pairs obtained from single standardizations.

The compressibility of water may be calculated from the above data in the usual way, after correction is made for the air displaced by the weight of water in excess of that used in the standardization.¹³ The four determinations yield values for $\beta_{\text{H}_2\text{O}, 25^\circ}$ of 41.55×10^{-6} , 41.60×10^{-6} , 41.45×10^{-6} , and 41.57×10^{-6} , with an average value of 41.54×10^{-6} .

¹³ The water correction factor is applied to differences of water as weighed in air and no correction for air displacement during weighing is necessary, but, since compressibility refers to true volume, appropriate correction for the air displaced by the water and the weights must be made.

Materials

Tellurium: An analysis showed 99.98% of tellurium;¹⁴ no attempt was made to determine the nature of the impurity present since it is known that impurities in such quantities have a negligible effect upon compressibility with the order of accuracy now attainable.

In order to eliminate voids as much as possible the tellurium was remelted in a Pyrex tube and cast in such a way as to form a single crystal.¹⁵ The tube was chosen of such a size that the casting obtained fitted closely to the piezometer barrel, in order that the quantity of water might be kept at a minimum. The castings obtained, length 22.0 cm. and diameter 1.5 cm., were beautifully crystalline, showing a series of parallel plane markings along which the crystal tended to crack, inclined steeply to the longitudinal axis.

The density was determined upon fragments of the crystal after the compressibility determinations had been made. The usual water displacement method was used with especial care to have possible fissures filled with water. This was done by first immersing the fragments in a large tube nearly filled with water and evacuating the free space. Under this treatment the air held by the crystal greatly expanded, and it became an easy matter to remove the bubbles formed. The crystals were then promptly transferred to a vessel of water in which they were to be weighed. Three determinations upon different pieces gave values for the density of tellurium of 6.258, 6.262, 6.262, average, 6.261, correction having been made for displacement of air.¹⁶

Determination of Compressibility

The compressibility data are given in Table II.

¹⁴ This material was very kindly furnished by Mr. Willis T. Burns, manager of the Raritan Copper Works, Perth Amboy, New Jersey. It had been refined from a cruder sample containing 1% of selenium.

¹⁵ The technique used by Bridgman, Ref. 3, was used here without modification.

¹⁶ Kahlbaum, *Z. anorg. Chem.*, 29, 289 (1902), found 6.235, and Beljankin, *J. Russ. Phys. Chem. Soc.*, 33, 670 (1901), found 6.338.

The figures here given have their usual significance. Each experiment yielded two (bracketed) figures, the first representing the descent from 500 to 100 megabars and the second the ascent from 100 to 500 megabars made without refilling. It was thought better to start at the higher pressure in order to set the stopper more firmly and quickly, for any progressive settling would cause a lack of coincidence between the two legs of the pressure-volume curve. The correspondence between the members of each pair of figures illustrates the reproducibility of the method, but comparison between separate determinations should be made with the average value for each pair. This is done in the last column of the table, and the agreement between the average values may be seen to be very close.

After a number of determinations had been made the tellurium was remelted and recast, and additional determinations were made in order to free the measurements from any suspicion of error occasioned by imperfections in the original casting. These are the last two determinations in Table II, and they agree with the preceding values within the limit of accuracy, though the first is probably somewhat low.

The average of these six determinations, 5.00×10^{-6} , which represents the average compressibility between 100 and 500 megabars, is probably accurate to within two in the second decimal place.¹⁷

Discussion

Fig. 1 shows that the value here determined for the compressibility of tellurium fits nicely upon a smooth curve through the corresponding values for tin, antimony, iodine and cesium when the elements are plotted along the abscissa according to atomic numbers, and that the order of the compressibility coefficients is the same as that of the atomic volumes.¹⁸

¹⁷ The value calculated by Bridgman from the linear compressibilities parallel to the trigonal axis and perpendicular to it, 5.082×10^{-6} , represents the initial compressibility at 30°, pressure taken in kg./cm.². This can be transformed to a value representing the average compressibility between 100 and 500 megabars at 25° by correcting for the difference in temperature, the difference in pressure units and the difference in pressure range. The first two corrections will tend to increase Bridgman's value, since the compressibility has been found to increase with falling temperature, and since the volume change per megabar is greater than per kg./cm.², but the third correction tends to decrease it, since the compressibility here decreases with increasing pressure. The corrected value is 5.12×10^{-6} , and is appreciably higher than the value determined here. Bridgman does not state how closely the axis measured corresponded to the true trigonal axis; a small variation would be sufficient to account for the discrepancy, since the coefficients for the two axes are so greatly different.

It would appear, therefore, that Richards' method is simpler for the determination of volume compressibility, since no attention need be paid to crystallographic orientation, though for this reason it furnishes no information whatever concerning compressibility anisotropy.

¹⁸ The atomic volumes have been calculated from the density data given in the International Critical Tables, Vol. I, page 103.

It is evident, therefore, that the mass of the nucleus has, so far as these measurements can show, a negligible effect upon compressibility. With the interpretation of the other periodic properties upon the basis of the extra-nuclear atom following the work of Moseley, compressibility, shown by Richards to be a periodic function, likewise received the common explanation. The significance of the present work, therefore, is chiefly one of emphasis and confirmation.

Fig. 1

Analysis of the curve given in Fig. 1 is beyond hope at present, and will probably not be made until the positions of the electronic orbits in each element and the interaction of the electrons, and also the directive interatomic forces, related to the crystal structure, are understood.

There now remains only to explain the remarkable negative coefficient of linear compressibility found by Bridgman. This effect was observed for tellurium alone, and Bridgman attempted no explanation.

The crystal structure of tellurium is well known.¹⁹ The atoms are arranged on a triangular lattice, the side of the unit basal triangle, a , measuring 4.445 Å., and the height of the unit prism, h , 5.912 Å. The

¹⁹ Slattery, *Phys. Rev.*, [2] **21**, 378 (1923). Bradley, *Phil. Mag.*, **48**, 477 (1924).

density of the element requires three tellurium atoms associated with each lattice point. These atoms are arranged around the prism edge to form an ascending helix, with a threefold symmetry, each atom exactly above the third atom below in the same helix; the prism edge is thus a screw-axis. The intersections of the axes of these helices with the basal plane form the unit basal triangles. This is the Sohncke point-system 23 or 24, the x-ray method being unable to make a decision between the two systems, which differ only in the direction of the screw. For the purposes of the demonstration given here it is immaterial whether the screw is right-handed or left-handed. The radius of the helix can be calculated from Bradley's data, and is 1.20 Å., representing the distance from the center of each atom to the axis of the helix.

There are thus two inter-atomic distances, namely, that between atoms in the same helix and that between atoms in different helices. As Bradley showed for selenium it may be shown for tellurium also that the distance between nearest atom centers in the same helix is much less than that between atom centers in different helices. For tellurium these values are 2.86 Å. and 3.46 Å., respectively. This doubtless means that the atoms in the same helix are held together by cohesive forces much greater than those binding atoms in different helices, and that the crystal is "harder" in the direction of the screw-axis than perpendicular to it. Bradley has pointed out that the uniqueness of this axis, present in both selenium and tellurium, doubtless accounts for many of the directional properties observed in the two elements, and that crystallization is probably preferentially along this axis. This was found to be the case by Bridgman, who states that the trigonal (screw) axis lay longitudinally in the casting.

It is evident that this crystal structure is not closely packed, and it is conceivable that a change in either of the major dimensions, that of the side of the unit basal triangle, a , or that of the prism edge, h , should cause a change in density resulting merely from a difference in the closeness of the packing of the atoms, the two inter-atomic distances remaining unchanged. In such a process a lengthening of the prism edge h would cause a shortening of a and also a shortening of the radius of the helix. If such an elongation would result in an increase in density, it is entirely reasonable to suppose that an increase in pressure, tending towards an increase in density, would in fact cause a lengthening of this axis, with an attendant shortening of the other two dimensions. Such a lengthening would obviously cause the abnormal coefficient observed by Bridgman.

Fig. 2 shows a curve representing density as a function of the height of the unit prism. The values from which the curve was plotted were calculated by taking a series of values for h and keeping the inter-atomic distances, 2.86 Å. and 3.46 Å., unchanged, calculating the radius of the

helix and the side of the unit basal triangle, a , and from these the density of the hypothetical crystal. The curve passes through a minimum at a density slightly greater than 6.20, corresponding to a value for h of 5.55 Å. For a prism of height less than 5.55 Å. an increase in pressure tending to cause an increase in density could do so only by shortening h , the two interatomic distances remaining unchanged, and the screw-axis would therefore show the usual positive compressibility coefficient. On the other hand, if the value for h lay to the right of 5.55 Å. an increase in pressure would cause a lengthening in h , since such a process would result in an increase in density. The actual value of h for tellurium, indicated by the arrow in the figure, is 5.91 Å. and is therefore to the right of the minimum, so that an increase in pressure should cause an increase in h , or, in other words, a negative compressibility coefficient along this axis.

Apparently no measurements have been made upon the compressibility of selenium along the screw-axis, but on the basis of the reasoning advanced here its behavior can be predicted. Fig. 3 is a curve for selenium similar to Fig. 2 for tellurium. The actual value for

h , indicated by the arrow, appears to lie very slightly to the left of the minimum, and therefore the height of the unit prism would very likely decrease with the application of pressure (assuming, of course, that the lattice dimensions used in the calculations are correct); but since the screw-axis is in a state of greater compression than the triangular axes the compressibility along this axis is probably low.

Resisting the elongation (or contraction) of the helix upon the application of pressure, there is the tendency within the lattice to maintain the angle formed by any three atoms in the same helix at (for tellurium) 126.5° , and this tendency doubtless becomes more and more urgent as the angle departs further and further from this value, so that it may be assumed that the adjustment of density by the lengthening or shortening of the helix meets with increasing resistance as the pressure rises. It

Fig. 2.—Tellurium.

is this restraint which prevents the helix from straightening completely upon the first application of pressure.

It is wholly possible, if the reasoning advanced here is valid, that other substances might be found to show negative coefficients of linear compressibility when the crystal structure permits an adjustment of packing similar to that in the case of tellurium. Structures such as those represented by the Sohncke point-systems 19 and 20, and 23 and 24, that is, possessing a screw-axis, should show this behavior when h is on the right (or left) of the minimum, though when the substance concerned is a chemical compound it is probable that the directive forces, presumably

here much stronger than in the elementary state, might offer much greater resistance to the elongation of the screw-axis.

In conclusion the authors wish to express their indebtedness to Professor F. W. Richards for the use of the apparatus and also for the kindly interest he has taken in the work.

Summary

1. The average cubic compressibility of tellurium between 100 and 500 megabars and at 25° has been found to be 5.00×10^{-6} , the significance of this result has been discussed.

2. An approximate value has been found for the compressibility of water at 25° , namely, 41.54×10^{-6} .

3. The negative coefficient of linear compressibility observed by P. W. Bridgman has been explained and a prediction made concerning the behavior of selenium. It is pointed out that a negative linear compressibility is not denied by the principle of Le Chatelier and that under certain conditions might be observed in other substances.

THE FREE ENERGY OF FORMATION OF PHOSPHINE

BY DAVID H. DRUMMOND

RECEIVED APRIL 25, 1927

PUBLISHED AUGUST 5, 1927

The elements that stand in the group between metals and non-metals have been studied very little from the standpoint of thermodynamics. Before 1923, no systematic study of the free energy of the compounds of silicon, phosphorus, boron, arsenic, antimony, tellurium and selenium had been made. The purpose of this investigation was to determine the free energy of formation of phosphine by the measurement of the thermal dissociation of the gas.

Experimental Part

Some preliminary experiments were made to determine the thermal decomposition of phosphine. It seemed probable that phosphine would decompose at low temperatures, since its homologs, arsine and stibine, do so. Some phosphine was passed through a glass tube which was heated near the center for a few minutes. The phosphine was then washed out with carbon dioxide and the ends of the tube closed off. When the tube was opened in a dark room a bright phosphorescence was apparent beyond the point where the tube had been heated. The gas is decomposed by heat and the phosphorus is condensed before it can recombine with the hydrogen.

If the temperature is kept slightly above the boiling point of phosphorus, equilibrium will result. If the gas is cooled quickly the phosphorus will condense before the recombination will have time to take place. The free energy of phosphine can, therefore, be determined by quickly cooling the gas after it has been heated and then determining the ratio of hydrogen to undecomposed phosphine.

The apparatus for the measurements consisted of a glass tube, enclosed in a muffle, through which dry phosphine was passed. The tube extended into a water-bath. On the end of the tube a potash bulb was placed, containing a saturated solution of copper sulfate. This tube absorbed the phosphine. The hydrogen was mixed with dry air at a T-joint and then passed through hot platinized asbestos. The water formed was

absorbed in a calcium chloride tube. The temperature was controlled by hand to $\pm 1^\circ$. Table I shows the results of these experiments.

Discussion

Solid white phosphorus at a temperature of 25° is the standard reference state for phosphorus. Since the measurements were made in the gaseous phase the free energy of fusion and vaporization must be known to calculate the standard free energy of formation.

Fig. 1. - Diagram of apparatus. M, muffle; W, water bath; P, copper sulfate bulbs; P. T., platinized asbestos; C, drying tube.

The heat capacity of phosphorus as given by Richards and Jackson is 5.24 from 85°K. to 293°K. The value 5.4 at 298°K. is given by Kopp. Equation (1) fits these data fairly well.

$$C_p(P_s) = 5.30 + 0.000341T \quad (1)$$

Because of lack of data it is necessary to assume that the law of Dulong and Petit holds for fused phosphorus. This is probably very near the truth since there is an increase in heat capacity after fusion. The heat capacity equation for fused phosphorus is

$$C_p(P_l) = 6.10 + 0.000341T \quad (2)$$

Using the value 160.0 cal. for the heat of fusion of phosphorus¹ the equation for the free energy of fusion is

$$\Delta F = -70 - 0.8T \ln T + 4.87T \quad (3)$$

For the standard free energy change in fusion this gives the value 13.1 cal.

Taking 12,600 cal.² for the heat of vaporization of phosphorus, and using the heat capacity equation for a quadri-atomic gas³ the general free-energy equation for vaporization is

$$\Delta F^\circ(4P_l, P_g) = 58,871.7 + 15.4T \ln T + 0.00033T^2 - 0.0000008T^3 - 203.7T \quad (4)$$

Equation (4) gives 6063 cal. for the standard free energy of vaporization of one gram atom of phosphorus. The entropy change in fusion and

¹ Landolt and Börnstein, "Tabellen," p. 1468.

² *Ibid.*, p. 1475.

³ Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923, p. 80.

vaporization can be calculated from the free-energy equation. The value 0.506 is obtained for the entropy change in fusion. The entropy change in vaporization is 25.5. Lewis and Randall⁴ give for the entropy of phosphorus gas the value 35.95. Subtracting the entropy changes of vaporization and fusion, the value 9.95 entropy units is found for the standard entropy of phosphorus.

Fig. 2.

Taking -4900 cal.^5 as the standard heat of formation of phosphine, and subtracting the heats of vaporization and fusion, the value $-17,660.5 \text{ cal.}$ is obtained for the heat change in the reaction:

Using the heat-capacity equations³ for the gases involved in the reaction, the general free energy equation is

$$\Delta F^\circ = -16,486.5 + 3.72T \ln T + 0.0004T^2 + 0.0000007T^3 + IT \quad (6)$$

The values of $\ln K$ given in Table I are calculated from equation (7) upon the assumption that the partial pressures of the gases are proportional to their mole fraction.

$$\Delta F^\circ = -RT \ln \frac{P_{\text{PH}_3}}{(P_{\text{H}_2})^{3/2} (P_{\text{P}_4})^{1/4}} = -RT \ln K \quad (7)$$

The mean value of I , as shown in Table I, is 2.52. The free energy of formation of phosphine from hydrogen and solid phosphorus at 298°K. , as calculated from equations (3), (4) and (6), is -3296.0 cal.

The entropy change in the reaction as calculated from the free energy

⁴ Ref. 3, p. 464.

⁵ Ref. 1, p. 1491.

equation is -27.72 . This value gives for the standard entropy of phosphine the value 52.4 entropy units.

If $-R \ln K$ is plotted against $1/T$, the slope of the curve is ΔH . This was done on a large scale plot between the limits 573°K. and 613°K. The points were somewhat scattered. A line drawn through the means of these points had a slope of $-20,200$ as compared with the value $-19,711$ cal., calculated from the equation for the heat of reaction.

In conclusion the author wishes to thank Dr. R. K. McAlpine for his kind help and encouragement in this investigation. Acknowledgment is also due to Mr. L. D. Anderson of the Riverton High School for his kindness in lending some of the apparatus used in these experiments.

Summary

1. The equations have been worked out for the free-energy change of fusion and vaporization of white phosphorus. The standard free energies of these changes have been calculated.

2. The dissociation of phosphine has been measured in the temperature interval 573°K. to 613°K. From this the free energy of formation of phosphine has been calculated.

3. The entropy change of vaporization and fusion and the standard entropy of phosphorus have been calculated. The standard entropy of phosphine has been calculated.

DISSOCIATION PRESSURES OF AMMONIUM ORTHOPHOSPHATES¹

By T. E. WARREN

RECEIVED APRIL 28, 1927

PUBLISHED AUGUST 5, 1927

Recent developments in the manufacture of ammonia² and phosphoric acid³ have demonstrated the possibility of the commercial use of ammonium phosphate as a fertilizer. As such it contains two of the fundamental plant nutrients in readily available form.⁴

The most economical starting state for ammonia is the gaseous and for phosphoric acid a concentrated solution, the latter because the heat of reaction is sufficient to dry the product. The various reactions of ammonia gas with phosphoric acid have been the subject of the following experiments made by the author.

¹ From a thesis submitted in partial fulfillment of the requirements for the degree of M. Sc. in McGill University.

³ Jacob, *ibid.*, **48**, 125-133 (1925).

⁴ Allison *Soil Science*, **5**, 1-80 (1918).

Knowing the dissociation pressures of ammonia over saturated solutions of mono- and di-ammonium phosphates it is possible to prepare a gas mixture with a partial pressure of ammonia lying between these values. By passing this mixture into phosphoric acid, mono-ammonium phosphate can be formed without producing any di-ammonium phosphate, even though the passage of gas is continued after all of the free phosphoric acid has been neutralized. A similar process is, of course, applicable to the manufacture of the di- and tribasic salts in the pure, dry state.

Mono-ammonium phosphate crystals made by the rapid neutralization of concentrated phosphoric acid contain hygroscopic, occluded acid. This may be neutralized without the formation of di-ammonium phosphate by drying with an air-ammonia mixture as mentioned above.

Since mono-, di- and tri-ammonium phosphates are made by the precipitation of the salts from saturated solutions, concentration is not a variable. Accordingly, the dissociation pressures were determined with the dry, powdered salts which, from thermodynamic reasoning, must have the same dissociation pressures as the saturated solutions. The temperature range of the measurements, 80–125°, was chosen to include the zone of precipitation and drying.

Materials

The mono-ammonium phosphate used in the determination of the dissociation pressure was Merck's c. p. This salt in solution was slightly acid to methyl red and was heated for several hours before using to dissociate any di-ammonium phosphate which may have been present. In this connection the author was misled by a preliminary experiment made with Kahlbaum's c. p. mono-ammonium phosphate which contained some of the secondary salt and in solution was neutral to methyl red.

The di-ammonium phosphate used in the measurements was Baker's c. p. It contained none of the tribasic salt.

No attempt was made to dry the two salts completely because moisture does not interfere with the air-saturation method of vapor pressure determinations.

Experimental

Measurements of the partial pressure of ammonia over mono- and di-ammonium phosphates were made with a type of air-saturation apparatus. A measured amount of air was passed at a uniform rate through a purifying train of soda lime and phosphorus pentoxide and thence to a constant-temperature well containing alternate layers of the finely powdered salt and glass wool. The gas then bubbled through an absorbing worm containing an excess of standard sulfuric acid. At the end of the run the excess acid was titrated and the partial pressure of ammonia calculated. The constant-temperature well was vapor-jacketed and benzene, water, toluene,

n-butyl alcohol and amyl alcohol were used for heating. The temperature could be controlled to 0.02° for the duration of a determination (about 2 hours) and the powder within the well was uniformly heated to the boiling point of the heating liquid. That equilibrium was reached was proved by making several runs at different rates for each temperature.

At 100° mono-ammonium phosphate had so small a dissociation pressure that it could not be measured, and even at 125° the pressure was only 0.05 mm.

The results of the di-ammonium phosphate experiments are shown in Table I.

TABLE I
DISSOCIATION PRESSURE OF DI-AMMONIUM PHOSPHATE

Temp., $^\circ\text{C}$.	1/Abs. temp.	Dissoc. press., mm. Hg.
80.24	0.002830	1.36
99.91	.002680	5.02
109.30	.002615	11.00
116.89	.002564	17.74
125.36	.002509	29.35

peratures is given in Fig. 1. Substituting values from the straight line of Fig. 1 in the equation

$$(\ln K_1 - \ln K_2) = \frac{DH}{R} \left(\frac{1}{T_1} - \frac{1}{T_2} \right) \quad (1)$$

the heat of reaction for the equation

is found to be 19,050 calories.

From Kopp's⁵ law the molal heat capacity of ammonia in a solid is 13.3 calories per mole, while in the gas phase⁶ it is given by the equation $8.04 - 0.0007T + 0.0000051T^2$. Hence the molal heat capacity of the products of equation (2) at 373°K. is $13.3 - 9.1 = 4.3$ calories less than that of reacting substances, and the heat of reaction is $4.3 \times 45 = 194$ calories greater at 80° than at 125°. Since this would make the curve in Fig. 1 concave to the origin, with a curvature of 1 per cent., the experimental values for four of the points are in nice agreement. The point corresponding to 100° lies below the curve and the discrepancy is not within the limit of experimental error. The standard solutions, volumetric apparatus and thermometers were used in the other measurements and carefully evaluated and the point is the arithmetic mean of six separate determinations, of which none varies more than 2 per cent. of its value from the mean

The dissociation pressure of tri-ammonium phosphate was too great to measure in the air-saturation apparatus so the determinations were made by the static method. They are less accurate than those of the di-ammonium phosphate because of difficulties introduced by water formation, possibly from the production of some metaphosphate at high temperatures, and slowness of absorption at pressures lower than atmospheric.

Since dry tri-ammonium phosphate was not purchasable, it was prepared from the dibasic salt in the apparatus itself by passing ammonia at 100° and 1 atmosphere pressure over it. The tube containing the dry tri-ammonium phosphate was then attached through a mercury seal to a mercury manometer and a current of pure dry ammonia gas bubbled over it and through the manometer. When the salt and the apparatus were dry and free from any foreign gas the tube was sealed off at a constriction.

Because of the prementioned difficulty of slow absorption, only points near or above atmospheric pressure were determined, and such lower values as were needed were found by extrapolation.

The values obtained are given in Table II. In view of their small number their accuracy justifies only an approximate calculation of the heat of reaction. Calculated as before, its value is 9400 calories for the reaction

To check the vapor-pressure determinations, pure mono-ammonium phosphate was prepared by passing a large excess of a 1 per cent. ammonia-air mixture through concentrated phosphoric acid at 110°. The product had a dissociation pressure of ammonia corresponding to mono-ammonium phosphate and in solution at 110° would absorb no ammonia from the 1 per cent. mixture. A product having the dissociation pressure of di-ammonium phosphate was obtained by lowering the temperature to 100° while the 1 per cent. mixture was passed through. Pure, dry tri-ammonium phosphate was made by treating di-ammonium phosphate at 100° with ammonia at 1 atmosphere pressure.

The writer wishes to thank Dr. Milton Hersey of Montreal for a scholarship which rendered the research possible and Dr. J. F. Snell for supervision and for the facilities afforded in Macdonald College.

Summary

The reactions of gaseous ammonia and phosphoric acid solutions have been studied in order to produce the three ammonium salts of phosphoric acid in a pure state.

To produce the desired salt with the exclusion of the others, a variation in the partial pressure of the ammonia gas was used. This necessitated the determination of the dissociation pressures of mono-, di- and tri-ammonium phosphates. The pressure of mono-ammonium phosphate over the range 80–125° was less than 0.05 mm.; that of di-ammonium phosphate was 1.4 mm. at 80° and 30 mm. at 125°. The partial pressure of tri-ammonium phosphate, determined less accurately, was 730 mm. at 110° and 1170 mm. at 125°.

Using the partial-pressure method, pure mono-, di- and tri-ammonium phosphates were prepared.

THE HEAT OF FORMATION OF AMMONIUM CARBAMATE FROM AMMONIA AND CARBON DIOXIDE

BY K. G. CLARK AND H. C. HETHERINGTON

RECEIVED MAY 2, 1927

PUBLISHED AUGUST 5, 1927

In the synthesis of urea from ammonia and carbon dioxide, the two reactants first combine to form ammonium carbamate as follows, $2 \text{NH}_3 + \text{CO}_2 \rightarrow (\text{NH}_3)_2\text{CO}_2$, with the liberation of a considerable quantity of heat. The present study was undertaken with the object of obtaining an accurate measure of this heat for use in such connections as the design and control of urea synthesis apparatus. Experimental determinations of this value have previously been made,^{1,2} and in addition there are available vapor-pressure data³ from which a value may be calculated, but examination of this material revealed discrepancies which would impair its usefulness.

The experimentally determined values range from 37,700 cal. to over 42,000 cal. per mole at constant pressure. An even wider variation is encountered as shown in Table I, when the heat evolved at constant volume is calculated from existing vapor-pressure data by means of the van't Hoff equation.

TABLE I
CALCULATED HEAT OF REACTION

Temp range, °C.	cal /g. mole		Source of vapor-pressure data
	Maximum	Minimum	
10.0- 30.0	36,670	36,200	Naumann ^{3a}
14.9- 30.0	39,510	32,290	Briggs ^{3g}
30.0- 50.0	39,170	38,510	Naumann ^{3a}
30.9- 44.9	38,280	36,660	Briggs ^{3g}
37.8- 49.6	35,540	31,710	Isambert ^{3c}
49.6- 67.6	40,350	31,750	Isambert ^{3c}
50.0- 60.0	38,460	30,820	Naumann ^{3a}
77.2-114.5	45,450	37,740	Briner ^{3e}
114.5-152.0	42,660	36,270	Briner ^{3e}
152.0-197.0	46,090	22,910	Briner ^{3e}

It will be seen that at temperatures above 30° the results become very erratic. This is no doubt due in the first place to the difficulties in making accurate pressure determinations at elevated temperatures,

and at the pressures encountered in the case of ammonium carbamate; secondly, to the tendency of the reaction $(\text{NH}_3)_2\text{CO}_2 \rightarrow (\text{NH}_3)_2\text{CO} + \text{H}_2\text{O}$ to take place during the time required for vapor-pressure measurements. Finally, the unknown extent of the variation from the perfect gas laws of a mixture of ammonia and carbon dioxide renders the data for the higher pressures untrustworthy.

Previous Experimental Methods.—Lecher⁴ determined the heat evolved in ammonium carbamate formation by determining heats of solution and heats of neutralization, obtaining 37,700 cal. at constant pressure, as follows:

Combining Reactions 1 and 2

Raabe¹ employed the direct method at one atmosphere, using a continuous flow of ammonia and carbon dioxide through a bulb contained in a calorimeter, and obtained 39,300 cal. The procedure adopted by Raabe introduced a number of sources of error, however, one of which was pointed out by Matignon,² namely, that some of the carbamate formed might be carried away by the exit gases and thus lead to too high a result. Moreover, the quantity of carbamate used was small (0.3–0.8 g.), the observed temperature rise, therefore, being too small for the greatest accuracy.

Matignon² determined the heat of solution of ammonium carbamate and the heat of neutralization of dissolved carbamate with hydrochloric acid, deducing the heat of formation of ammonium carbamate from ammonia and carbon dioxide as 39,000 cal., at constant pressure. The data required in addition to those determined by Matignon, as well as their source, were not disclosed.

The direct method possesses advantages over other means, provided such sources of error as loss or insufficiency of material can be eliminated. In the direct method as adopted in the present study, loss of material was avoided by use of a closed system; the amount of carbamate formed was approximately 5 g., the temperature rise being sufficient to minimize observational error.

Apparatus and Procedure

The principal parts of the apparatus are shown in Fig. 1. A fully charged carbon dioxide cylinder A was connected to Cylinder B so that the latter could be brought to about 41 atmospheres' (610 lbs.) gage-pressure at the beginning of each experiment. Analysis showed the presence of less than

⁴ Lecher, *Sitzb. kgl. preuss. Akad. Wiss.*, II, Abth. October, 1878.

0.03% of moisture in the carbon dioxide. Further drying of the gas was not resorted to, since some moisture is required to enable the reaction to proceed; moreover, the possible influence of the amount found above could not be greater than 100 cal. per mole of carbamate. Twelve and two-tenths meters of small copper pressure tubing led from Cylinder B to Valve F, being immersed in the form of a coil D in the constant-temperature bath C. The tubing H from Valve F to the water level in the calorimeter was insulated to minimize radiation losses at this point. The bomb I of 415cc. capacity was fitted with a valve G which could be opened or closed by means of a small key inserted through a hole in the calorimeter cover.

Fig. 1.

At the beginning of an experiment, the bomb was evacuated to a pressure of approximately 5 mm. of mercury, and anhydrous synthetic ammonia was admitted to a pressure of approximately 6.8 atmospheres absolute, which is about 1.7 atmospheres below saturation pressure at 21° . Higher pressures of ammonia were intentionally avoided to eliminate possible error through condensation of ammonia, and its subsequent vaporization during the determination. The bomb was then immersed in the calorimeter and connected to the carbon dioxide supply line at Valve F. The temperature of the room, the bath C, the calorimeter and the jacket having been brought to $21^{\circ} \pm 0.1^{\circ}$, the stirring rise over a preliminary period of six minutes was observed. At the end of this time, carbon di-

oxide was admitted by opening successively Valves F and G. To insure that the heat effect of expansion of the carbon dioxide would be reproducible in all experiments and measured in the calorimeter, the capillary tube J had been introduced as an orifice. The pressure attained equilibrium at approximately 40 atmospheres in about two minutes, Valves F and G being closed one minute later. Temperature readings were taken at 15-second intervals during the transfer period of about six minutes, after which the final cooling rate was determined. The amount of carbamate formed was determined by analysis, it being assumed on the basis of the relatively low vapor pressure of carbamate at 21° that the ammonia was completely combined in the presence of the large excess pressure of

Fig. 2.—Carbon dioxide compression experiment. Initial pressure, 0.005 atmospheres (air); final pressure, 42.496 atmospheres (carbon dioxide), heat evolved, 427.0 cal

carbon dioxide employed for this purpose. The carbamate was collected under such conditions that the possibility of loss was entirely precluded, the excess of carbon dioxide being discharged and the bomb evacuated through standard acid. Water was then admitted to the bomb to dissolve the carbamate, and the solution withdrawn under vacuum with the standard acid trap in series. After several washings had been carried out in this manner to insure complete recovery, the solution of carbamate was made up to volume and analyzed for ammonia, the standard acid being back-titrated.

The "water equivalent" of the complete calorimeter assembly containing 1600 g. of water was determined in a preliminary series of experiments, in which a measured amount of heat was introduced electrically. The d. c. ammeter and voltmeter used were checked against instruments

of known accuracy, and during the heating period of five minutes these instruments were read at five-second intervals. The values obtained in four experiments ranged from 2071 to 2078 g. of water, or an average of 2075.

In a second series of preliminary experiments, the heat effect of the introduction of the carbon dioxide into the calorimeter bomb was measured in the absence of ammonia. For this purpose, the bomb was evacuated, immersed in the calorimeter and carbon dioxide was admitted to a pressure of 40 atmospheres' gage, the technique being identical with that to be used in later experiments with ammonia present. It was realized that in the

Fig. 3.—Expt. 14. Heat of reaction, $2\text{NH}_3 + \text{CO}_2 \longrightarrow (\text{NH}_3)_2\text{CO}_2$; initial pressure, 7.122 atmospheres (ammonia); final pressure, 42.633 atmospheres (carbon dioxide).

later experiments with ammonia present, the total amount of carbon dioxide entering the bomb would include the additional quantity required to react with the ammonia. This correction was subsequently calculated, for it could not be determined directly. The temperature rise observed in three experiments⁶ was 0.202, 0.204 and 0.207°, or an average of 0.205°, corresponding to the liberation of 427 cal. Fig. 2, which typifies these experiments, clearly shows the initial temperature drop due to the Joule-Thomson effect taking place within the calorimeter. It is interesting to note that the above value of 427 cal. is in good agreement with that obtained from theoretical considerations, which was 448 cal. This latter value was arrived at by calculating the Joule-Thomson effect at the orifice and the heat of compression in the bomb.

⁶ For convenience, these experiments will be referred to as carbon dioxide blanks.

Experimental Data and Method of Calculation

Table II and Fig. 3 present the time, temperature and other observations taken during a determination of the heat of reaction (Expt. 14). This material will be used to illustrate the procedure followed in the final calculations.

The heat evolved by the formation of the carbamate may be expressed by the following equation, which takes into account the necessary corrections.

Heat evolved = $(A + B)(x + y + z) - C(x + y) - D = (1.345 + 0.0025)(2075 + 8.24 + 2.42) - 0.205(2075 + 8.24) + 26.3 = 2409.6$ cal., where A is the temperature rise of the transfer period after correction of the Beckmann readings for deviation of the latter from a Bureau of Standards compared thermometer;

$$B \text{ is the Regnault-Pfaundler cooling correction} = T_{tr} \left[V_p + \frac{V_c - V_p}{\theta_c - \theta_p} (\theta_{tr} - \theta_p) \right] = 6.25 \left[-0.00117 + \frac{0.00217 + 0.00117}{2.694 - 1.326} (2.380 - 1.326) \right] + 0.0025^\circ$$

T_{tr} is the time of the transfer period in minutes;

V_p , the cooling rate of preliminary period;

V_c , the cooling rate of final period;

θ_c , the mean temperature of final period;

θ_p , the mean temperature of preliminary period;

θ_{tr} , the mean temperature of transfer period;

C is the temperature rise (corrected as for A) of the transfer period in the carbon dioxide blank;

D , the Joule-Thomson effect in calories of that part of the carbon dioxide which enters into the reaction to form carbamate = $\Delta T N_1 C_{P_{CO_2}} = \mu N_1 C_{P_{CO_2}} (P - P_0) = (-1.15)(0.0665)(8.79)(42.8 - 3.7) = -26.3$ cal.;

T is the change in temperature in $^{\circ}\text{C}.$ of the carbon dioxide expanding through orifice J from mean effective pressure P of the carbon dioxide, at the source, against the mean pressure (P_0) of the ammonia in calorimeter bomb $= \mu(P - P_0) = -45^{\circ}$;

μ = Joule-Thomson coefficient for carbon dioxide $= -1.15^{\circ}$ per atmosphere;

N_1 = number of moles of entrant carbon dioxide combining to form carbamate;

$CP_{\text{CO}_2} = 7.0 + 0.0071 T + 0.00000186 T^2 = 8.79 \text{ cal.} = \text{molal heat capacity of carbon dioxide at mean of calorimeter and entrant gas temperatures;}$

x = heat capacity of the calorimeter assembly as determined $= 2075 \text{ g. cal. per deg.};$

y = heat capacity of the carbon dioxide in bomb (in excess of that required for the reaction) $= N_2 CP_{\text{CO}_2} = (0.922)(8.93) = 8.24 \text{ g. cal./deg.};$

N_2 = number of moles of carbon dioxide in excess of that required for the reaction (from van der Waals' equation of state);

C_P = molal heat capacity of carbon dioxide at 22° .

z = heat capacity of the carbamate formed $= N_3 CP_{(\text{NH}_4)_2\text{CO}_2} = 0.0665 (36.4) = 2.42 \text{ g. cal./deg.};$

N_3 = number of moles of carbamate formed $= 0.0665$;

$CP_{(\text{NH}_4)_2\text{CO}_2}$ = molal heat capacity of carbamate calculated from the molal heat capacities of the elements using the values $\text{C} = 1.8$, $\text{H} = 2.3$, $\text{O} = 4.0$, $\text{N} = 6.4$, assigned by Kopp⁶ $= 36.4 \text{ g. cal./mol./deg.}$

The 2409.6 cal. found as above is referred to the quantity of carbamate found by analysis, which in this case was 1.8624 g. of nitrogen, equivalent to 5.1892 g. or 0.0665 mole of carbamate; from which we obtain $\Delta U_p = 2409.6/0.0665 = 36,250 \text{ cal.}$ Five determinations gave the following results: 36,340, 36,350, 36,100, 36,250 and 36,480 cal., or an average of 36,300 cal.

The heat of reaction at constant pressure may be calculated from the above-determined value by the usual equation $\Delta U_p = \Delta U_v - \Delta nRT$, where Δn is the difference between the final and initial number of gas moles involved. The value thus obtained is 38,060 cal.

Summary

The heat of formation of ammonium carbamate from ammonia and carbon dioxide has been determined as 36,300 cal. per mole of carbamate at constant volume. This value, which was obtained by the direct method, is appreciably lower than previous experimental values, with the exception of Lecher's result of 37,700 cal. at constant pressure. It may also be noted that the value calculated from Naumann's vapor-pressure data in the range where accuracy of the latter might be expected (10 – 30°) is in good agreement with the results of the present study.

THIOGLYCOLIC ACID AS A COLOR TEST FOR IRON

BY EDWARD LYONS

RECEIVED MAY 2, 1927

PUBLISHED AUGUST 5, 1927

The standard method for the identification of ferric iron is the thiocyanate method. The test is based on the red color formed when an alkali thiocyanate reacts with ferric iron in acid solution. This method, with various modifications, is used for the determination of small amounts of iron.

For the detection of ferrous iron in minute quantities, the dark blue ferrous ferricyanide test is used. This serves to indicate the presence of ferrous iron in ferric solutions.

The test under consideration in this paper is the color produced when the reaction mixture between thioglycolic acid and iron in solution is made faintly alkaline. The color so produced has long been known. Andreasch¹ described it in detail and Claësson² claimed that he was quite aware of the reaction. The interpretation of the reaction, however, we believe to be entirely different from what they claim. They believed that the color produced was due to the formation of the complex ferric thioglycolate, $\text{Fe}(\text{SCH}_2\text{COONH}_4)_3$. They further observed that the color faded after some time but was regenerated on shaking the solution with air. The fading of the color, they thought, was due to oxidation of part of the acid which then gave a colorless ferro salt. This in turn took up oxygen and gave the colored ferri salt. We differ entirely with the explanation of the mechanism of the color reaction as given by the above-mentioned investigators. The test has been found to be general for both ferric and ferrous iron. The red or purple color produced, however, is due to the reaction between ferrous iron and thioglycolic acid. In alkaline solution the color produced is pink in dilute solutions and intensely red-dish-purple in the more concentrated solutions. The test is applicable quantitatively in dilutions approximating one part of iron in about five million. Qualitatively, iron can be detected even in dilutions of 1:10 or 12 million. With thiocyanate the quantitative estimation of ferric iron in dilutions greater than several parts of iron per million presents considerable difficulty in color matching.

When ferric iron in concentration greater than 1:100,000 is present, the addition of thioglycolic acid yields a transient blue coloration. When the concentration is less, only a flash of blue may be observed. This is due to the formation of ferric thioglycolate, $\text{Fe}(\text{SCH}_2\text{COOH})_3$. However, this is at once reduced to the colorless ferrous thioglycolate, Fe -

¹ Andreasch, *Ber.*, 12, 1391 (1879).

² Claësson, *Ber.*, 14, 411 (1881).

$(\text{SCH}_2\text{COOH})_2$, complex, which yields the intensely colored ferrothioglycolate ion, $\text{Fe}(\text{SCH}_2\text{COO})_2^{--}$, in alkaline solution. If thioglycolic acid is similarly added to a solution of ferrous iron the blue coloration does not appear at all, but an intense red color is formed on making it alkaline. The presence of an oxidizing substance prevents the formation of the color. This is probably due to the formation of dithioglycolic acid, which does not yield color with either ferrous or ferric iron; its formation is the cause of the color fading observed by the previous investigators. The color cannot be regenerated by "shaking with air" nor by passing oxygen gas through the solution. On the contrary, fading of color results and when all of the thioglycolic acid has been oxidized the color can be brought back only by addition of more thio acid, or by means of a reducing agent which regenerates the thio acid in solution. Using ferric iron in the test and discharging the color formed with concd. hydrochloric acid, we no longer obtain a test for iron with thiocyanate, thus showing that the iron has been reduced to the ferrous condition. The addition of a drop of peroxide also discharges the color. It oxidizes not only the thio acid, but in the resulting solution thiocyanate gives a test for ferric iron.

The mechanism of the reaction between ionic iron and thioglycolic acid is probably best expressed as follows.

Reaction 1 occurs only when Fe^{+++} is present. As soon as it is reduced, Reaction 2 takes place, yielding the colored ion when an alkali is added. However, if an excess of acid or alkali is added the color is discharged. Neutralization of the excess reagent added again brings out the color.

Although the reaction is between ferrous iron and thioglycolic acid, both ferric and ferrous iron may be detected and estimated in the same solution. The color with thiocyanate due to ferric iron, which is stable in acid solution, is readily discharged by alkalis, while that produced by thioglycolic acid is stable in weakly alkaline solutions. Strong bases have to be used with considerable care, since a small excess discharges the color. Ammonia, however, does not appear to affect the intensity of the shade quickly, even when present in great excess. In time, however, a too great amount will show its effect. Since thioglycolic acid reduces ferric to the ferrous form, the total iron present can be readily estimated. The ferric iron can be determined with thiocyanate and the ferrous iron is then obtained by difference.

Qualitative Test.—To about 5 cc. of the suspected neutral or slightly acid solution free from oxidizing agents (these oxidize the thio acid), add one drop of thioglycolic acid and about 0.5 cc. of concd. aqueous ammonia.

If no color appears in about five minutes, no ionic iron is present in concentration greater than 1 to 10 or 12 million. When iron is present in concentration of 1 to 4 or 5 million or greater, the color appears at once. If it is of interest to know whether any ferric iron is present, a test with thiocyanate can be made first; then a drop of thioglycolic acid is added, and on addition of aqueous ammonia, in excess, the color due to ferric iron (if present) fades and the purple or pink color due to the ferrous-thioglycolic acid reaction appears. When the ammonia is added before the thio acid the maximum intensity of color appears somewhat more slowly.

The intensity of the color obtained with different concentrations of iron solutions led us to believe that the method would be applicable quantitatively. Accordingly, a series of solutions was made containing one part of iron in 100,000, 200,000, 300,000, etc., up to 12 millions. These were then used as unknowns. It was found that the difference between every two dilutions could be very easily detected and the particular concentration dealt with absolutely determined by comparison with known standards of similar solutions up to about 1 in 4 or 5 million parts. In greater dilutions the results were only qualitative. From these results we were able to develop a method for the determination of ferrous and ferric iron in any solution.

Quantitative Estimation of Total Iron (Ferric plus Ferrous)

(a) **Total Iron.**—The unknown solution is first tested qualitatively. From the intensity of the color obtained, a little experience soon teaches the experimenter to approximate the correct concentration. The dilution is then adjusted to about 1:500,000. When the solution is already very dilute the determination is made on the original, if feasible, or the solution is concentrated by evaporation. In the present work the color produced at about 1:500,000 was used. At this dilution the colors obtained are very easy to match, and the difference in intensity between, say 475,000 and 500,000, is distinct enough to allow an approximation of the intermediate dilutions very nicely. The solution prepared for testing is then transferred to a test-tube marked at 5cc. volume. To this is now added one drop of thioglycolic acid and 0.5 cc. of concd. aqueous ammonia. The color produced is then compared with the colors of standards of known concentration of iron. We then have: $\% \text{ Fe in unknown} = 100 \times \frac{\text{dilution of unknown}}{\text{dilution of standard}} \div \text{amount used (g. or cc.)}$; multiplying by 10,000 we have parts per million; that is, if 1.0 cc. of an unknown is diluted to a final volume of, say, 5000 and compared with a 1:400,000 standard, then $\% \text{ Fe in unknown} = 100 \times (5000/400,000) \div 1 = 1.25$, or 12,500 parts per million.

Likewise, if 0.2 g. of substance is dissolved to give a solution containing one part in 10,000, and the color of this agrees with that of a 1:300,000 standard, then $\% \text{ Fe} = 100 \times (10,000/300,000) \div 0.2 = 0.067$.

(b) **Ferric Iron.**—By using potassium thiocyanate in a hydrochloric acid solution of the unknown and comparing with colors of standard solutions, the ferric iron may be estimated as usual. If the sample at hand is not of sufficient quantity to permit a separate determination, then both ferric and ferrous iron may be determined in the one sample before the estimation of the "total iron." A drop or two is tested with potassium thiocyanate. If ferric iron is indicated, a quantitative estimation on the major part of the sample is made. This gives us the ferric iron. To this solution is now added a few drops of aqueous ammonia, to discharge the color due to ferric iron, the ammonium hydroxide is neutralized with hydrochloric acid, since it delays the appearance of the color, then one drop of thioglycolic acid is added. Ammonium hydroxide now added in slight excess gives the color due to the total iron reduced to the ferrous condition.

(c) **Ferrous Iron.**—From the total iron (estimated as ferrous) subtract the ferric iron (potassium thiocyanate method). The difference is the ferrous iron originally present.

TABLE I
DETERMINATION OF IRON IN SOME SAMPLES

Substance	Iron found	Iron by analytical method, or calcd.	Remarks
Sol. Fe Chloride	10.0%	10.2%	
Colloidal Fe Soln.	0.0114 g. per cc.	0.0119 g. per cc.	Decomp. with HCl
$\text{FeSO}_4(\text{NH}_4)_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$	14.02%	14.25%	
U. S. P. Iron Quinine Citrate	12.5%	$13.00 \pm \%$	
Iron Cacodylate	0.00155 g. per cc.	0.00160 g. per cc.	

TABLE II
ANALYSIS OF MIXTURES OF FERROUS AND FERRIC IRON

Mixtures containing known amounts of ferric and ferrous iron were made. Ferric iron was determined by the potassium thiocyanate method. Total iron was obtained by the thioglycolic acid method. The difference gave the ferrous iron.

Ferric iron, g.		Total iron, g.		Ferrous iron, g.	
Taken	Found	Taken	Found	Taken	Found by diff.
0.0001	0.0001	0.00015	0.00016	0.00005	0.00006
.00018	.0002	.00026	.0003	.00008	.00010
.00004	.000036	.00018	.00018	.00014	.000144

The following substances (0.01 g. per cc. of 1:500,000 ferric solution) did not appear to affect the delicacy of the reaction.

Sodium acetate, arsenate, bromide, benzoate, citrate, cacodylate, chloride, fluoride, glycerophosphate, iodide, phosphate, pyrophosphate, salicylate (use three or four drops of thio acid), sulfate, sulfite, sulfocarbolate, thiosulfate, etc.

Also salts of the following metals: potassium, lithium, barium, calcium, strontium, and, if not in too large amounts, mercury, copper, cadmium, zinc, tin, magnesium, silver, bismuth, etc. When these are present in the order of the concentration of the iron no interference is observed (especially when three or four drops of thio acid are used). Large amounts (0.001 g. per cc. or more) which of themselves give a color with the acid or tend to precipitate with aqueous ammonia may affect the delicacy of the test. The addition of some sodium citrate will in such cases often bring out the full color due to the iron present.

Summary

Thioglycolic acid is recommended as a delicate color test for iron. This reagent³ is capable of detecting iron in dilutions up to 1:10,000,000 and is relatively much more delicate than the usual thiocyanate test. Moreover, the test is independent of the state of oxidation of the iron since it is given equally well with either ferrous or ferric iron in contrast with the thiocyanate test which is sensitive only to ferric iron.

A study of the reaction of thioglycolic acid with iron has shown that the reagent is really a test for ferrous iron, but since the reagent itself promptly reduces ferric iron to the ferrous state we have here a general test for ionic iron.

Since the thioglycolic acid test is applied in ammoniacal solution, a condition under which the color obtained with ferric iron and thiocyanate is completely discharged, the two tests may be applied to the same solution in succession.

The thioglycolic acid test is capable of quantitative application. Used in conjunction with the thiocyanate test we have here a simple method of estimating both ferric and ferrous iron in the same solution by colorimetric methods.

**DIFFUSION-POTENTIAL MEASUREMENTS APPLIED TO
HYDROCHLORIC ACID-GELATIN SYSTEMS. I. THE
EQUIVALENT WEIGHT OF GELATIN¹**

BY ALFRED L. FERGUSON AND EGBERT K. BACON

RECEIVED MAY 5, 1927

PUBLISHED AUGUST 5, 1927

In this article an apparatus is described which permits the approximate measurement of a static liquid-junction potential between hydrochloric acid of two concentrations and of more complex systems of hydrochloric acid-sodium chloride. The measurements are also extended to systems of hydrochloric acid-gelatin. The striking similarity between these systems and those of hydrochloric acid-sodium chloride favors the establishment of gelatin-acid solutions as true solutions. The stoichiometric character of the combination between gelatin and acid is demonstrated and the equivalent weight of gelatin determined.

If two different electrolytic solutions are placed in contact, there is developed at the junction a potential difference which is called a diffusion potential. This potential is caused by the unequal migration velocities of the ions in the two solutions, that is, in simple electrolytes or mixtures of electrolytes the potentials are determined by the ionic activities and the ionic mobilities.

In a boundary such as

the potential is zero since identical solutions are on each side of the contact layer. If, however, sodium hydroxide replaces part of the hydrochloric acid in one of the solutions in such a manner that the mixture always has a constant concentration of 0.10 *N*, a potential develops which becomes increasingly greater as the solution ultimately approaches 0.10 *N* sodium chloride, since the hydrogen ion is being replaced by the slower-moving sodium ion.

If in an identical arrangement as the above gelatin is substituted for the sodium hydroxide, the resulting potentials should give some information as to the physical state of the resulting mixtures, that is, whether as Loeb and others have maintained, gelatin reacts stoichiometrically with hydrochloric acid, forming highly ionized gelatin chloride,² or whether an adsorption complex of some sort is formed,³ or whether the type of

combination might be due partly to purely chemical forces and partly to forces of adsorption, as Hoffman and Gortner suggest.⁴

In order to carry out such measurements it was necessary to devise an apparatus that would permit the measurement of such potentials between solutions of high viscosity. Its reliability was first demonstrated with simpler electrolytic solutions.

Hydrochloric Acid Cells

The apparatus used in the investigation is illustrated by Fig. 1. A and B are two glass vessels filled with solutions M and M'. CGD is a three-way stopcock of 9 mm. bore. The two siphon arms are indicated.

Fig. 1.—Apparatus with saturated potassium chloride electrodes for the measurement of diffusion potentials.

E and F are dropping funnels and S and S' saturated potassium chloride electrodes. The liquid junction was made in the stopcock between the two siphon arms by proper manipulation of the stopcock and the application of suction through G.

Potential measurements were first made with a simple boundary which is illustrated by the following cell,

Such a cell is made up of five potentials e_1 , e_2 , e_3 , e_4 and e_5 . Potentials e_1 and e_5 are equal and oppositely directed, and the same is considered

⁴ Hoffman and Gortner, "Colloid Symposium Monograph II," Chemical Catalog Co., New York, 1925, p. 209. This work has been criticized by Cohn, *Physiol. Rev.*, 5, 349 (1925).

approximately true for e_2 and e_4 .⁵ Hence, the measured total potential of such a cell must be due almost entirely to the diffusion potential e_3 .

The potential measurements were made by means of a Queen Gray Standard type potentiometer which gave readings to 0.01 mv. The standard cell was a Weston cadmium cell which was checked against another cell certified by the Bureau of Standards. All measurements were carried out in an oil thermostat at 25° regulated to $\pm 0.015^\circ$. Observations were made by means of a telescope placed 12 feet from a Leeds and Northrup galvanometer No. 2500E with a sensitivity of 362 megohms.

The calomel-electrode vessels were of the Lewis type.⁶ The usual precautions were taken in making up the saturated potassium chloride electrodes and only the purest of chemicals used. The electrodes were checked with each other frequently and usually showed potentials below 0.10 mv. If at any time two reference electrodes showed potentials greater than 0.20 mv. they were discarded.

The hydrochloric acid solutions were made by dilution of a stock solution of 1 *N* hydrochloric acid which in turn was made from a standard, analyzed hydrochloric acid solution.

The concentration cells were made up and left in the bath for at least one hour before measurements were taken. When a cell had attained the temperature of the bath the stopcock was opened, the liquid junction established and a reading taken immediately. The stopcock was then closed. Another reading was taken shortly afterward. In all cases readings were taken with stopcock open; then the stopcock was immediately closed. Readings were taken in this manner at approximately hour intervals, until the potential of the cell started to drop rapidly. This usually resulted after a period of 40 hours.

The results obtained were very satisfactory. Three cells gave average values of 38.08, 38.08 and 38.11 mv. over a period of about 35 hours. These values represent the averages of about 20 readings taken over this period. The "time effects" were not large, amounting to less than 0.5 mv. It may be concluded, therefore, that the apparatus is capable of giving constant and reproducible potentials with this simple type of boundary.⁷

⁵ Loomis and Acree [*Am. Chem. J.*, **46**, 585 (1911)], Fales and Vosburgh [*THE JOURNAL*, **40**, 1291 (1918)] and others have shown that the diffusion potential between saturated potassium chloride and solutions of hydrochloric acid and sodium chloride below 0.1 *N* is zero or at any rate very small, that is, the order of a few tenths of a millivolt. More recently, Scatchard [*ibid.*, **47**, 696 (1925)] claims that the potential between saturated potassium chloride and concentrations of hydrochloric acid below 0.1 *N* is constant and has the value of 4.7 mv.

⁶ Lewis, Brighton and Sebastian, *ibid.*, **39**, 2245 (1917).

⁷ Calculated values of this boundary, by the Nernst equation indicate that the potential closely approximates 38 mv.

Hydrochloric Acid-Sodium Chloride Cells

The cells next studied were of the general type,

The cells were made up of four solutions A, B, C and D. A represents 0.10 *N* hydrochloric acid, the same in all of the cells; B represents a mixture of hydrochloric acid and sodium chloride of total concentration 0.10 *N*, in which *x* varies in different cells from 0 to 0.10; C represents a mixture of hydrochloric acid and sodium chloride of total concentration 0.01 *N*, in which *y* is equal to *x* until the value 0.01 is reached and then remains constant while *x* in the other solution changes until it reaches its final value of 0.10; D represents a solution of 0.01 *N* hydrochloric acid, the same in all cells.

The sodium chloride solutions in the mixtures were formed by partial neutralization of the hydrochloric acid. The sodium hydroxide used for this purpose was made by dilution of the solution formed by the electrolysis of sodium amalgam. Its concentration was determined by titration with hydrochloric acid.

Fig. 2.—Arrangement of cell for diffusion potential measurements.

The total potential of the above cell is made up of three different diffusion potentials E_1 , E_2 and E_3 at the solution contacts A-B, B-C and C-D. The cell shown in Fig. 1 permits the measurement of a single diffusion potential. By means of three such cells joined together, and with the use of four saturated potassium chloride electrodes, it is possible to measure each of the three boundary potentials E_1 , E_2 and E_3 individually, or combinations of the three. The arrangement of the cell is illustrated by Fig. 2.²

The method of setting up the cells and the manner of taking the readings were exactly as described for the hydrochloric acid cells. After the cell had attained the temperature of the bath, readings were taken at hour intervals for a period of about 12 hours.

Table I serves as a typical example of the results obtained with Bound-

² It is apparent that each diffusion potential involves the measurement of perhaps three boundaries, but the two boundaries $\text{satd. KCl} \mid \text{solution}$ and $\text{solution} \mid \text{satd. KCl}$, as noted before, probably have but little influence on the principal potential; hence, the diffusion potential is closely approximated in each case.

ary E_1 . This is characteristic of the results with Boundaries E_2 and E_3 . In the table the type cell is indicated at the top and the arrow from left to right indicates the direction of positive current through the cell. Duplicate cells were measured for each boundary and these are labeled Cell A and Cell B. The first entry under "Time" gives the hour at which the cell was first placed in the bath.

A summary of the measured values obtained with the various cells and the different boundaries is given in Table II. Col. 1 indicates the particular boundary measured; Col. 2, the value for the initial reading with Cell A; and Col. 3 the average of all readings for Cell A. Cols. 4 and 5 give similar readings with Cell B. Col. 6 gives the average of values in Cols. 3 and 5, and Col. 7, the averages of Cols. 2 and 4. The figures in parentheses after the potential values in Cols. 3 and 5 indicate the number of readings with the corresponding period in hours which the average value represents. For instance, (11-12) means 11 readings over a period of 12 hours.

An examination of the tables shows that the diffusion potentials of these more complex boundaries are as accurately reproducible as those of simpler systems, and in most instances appreciable "time effects" are not noticeable.

Hydrochloric Acid-Gelatin Cells

The hydrochloric acid-gelatin cells were of the following type,

TABLE II
SUMMARY OF POTENTIALS FOR VARIOUS DIFFUSION BOUNDARIES

These cells were made up of four solutions, A, B, C and D. A represents a solution of 0.10 *N* hydrochloric acid, the same in all cells. B represents a solution of $x\%$ gelatin in 0.10 *N* hydrochloric acid, in which x is the number of grams of gelatin present in 100 cc. of solution, and varies from 0 to 17.4 in the different cells. C represents a solution of $x\%$ gelatin

Fig. 3.—The diffusion potentials for boundaries $E_2(G)$, 0.10*N* HCl + $x\%$ gelatin | 0.01*N* HCl + $x\%$ gelatin; $E_3(G)$, 0.10*N* HCl + $x\%$ gelatin | 0.01*N* HCl; $E_1(G)$, 0.10*N* HCl | 0.10*N* HCl + $x\%$ gelatin.

in 0.01 *N* hydrochloric acid, where x again represents the number of grams of gelatin in 100 cc. of solution and varies between the limits 0 and 17.4 in the different cells. D represents a solution of 0.01 *N* hydrochloric acid, the same in all cells.

The total potential of this cell is made up of three diffusion potentials formed by the contacts of Solutions A and B, B and C, and C and D.

These are E_1 (G), E_2 (G) and E_3 (G) as indicated. Four saturated potassium chloride electrodes, one dipping in each solution, permit the measurement of any boundary or combination of boundaries.⁹

The hydrochloric acid solutions were made by dilution of an analyzed solution of 1 *N* hydrochloric acid, as described with the previous cells.

The gelatin was a pure ash-free (0.04% ash) iso-electric gelatin obtained from the Research Laboratories of the Eastman Kodak Company. The moisture content of the gelatin was about 12.6%. This was determined by heating 2 to 3g. samples in the drying oven at 110° until constant weight was obtained. The moisture content was applied as a correction to all weighings of gelatin.

A uniform procedure was used in preparing the gelatin solutions. The manner in which a 2% solution (which corresponds to a 1.75% solution when the moisture correction is applied) of gelatin in 0.10 *N* hydrochloric acid was prepared serves as an illustration of the general way in which all solutions were obtained.

Ten g. of gelatin (8.74 g. of the dry gelatin) was weighed to the nearest milligram. This was dissolved in distilled water at a temperature of about 35°. The solution of gelatin was then poured into a 500cc. flask and water added so that the volume was between 300 and 400 cc. A volume of 50 cc. of 1 *N* hydrochloric acid was then run in by means of a calibrated pipet and water was added to bring the volume to 500 cc. The solution of 2% gelatin in 0.01 *N* hydrochloric acid was made up in exactly the same way, 50 cc. of the 0.10 *N* hydrochloric acid being used instead of 1 *N* hydrochloric acid.

There was no difficulty encountered in making up these solutions, although with higher concentrations of gelatin they were very viscous and set to gels within a short time. The gel was easily melted by placing the flask in warm water. After this procedure it would not set to a gel until some time afterward, so that there was no trouble in filling the cells and making the boundaries.

The cells were filled and the boundaries made in exactly the same manner as previously described with the hydrochloric acid-sodium chloride cells. Readings were extended over a much longer period than with the other systems, usually over 24 hours. Since it seemed desirable to experiment with these cells under as rigorous conditions as possible, so that any consistent or reproducible results which might be obtained could not necessarily be ascribed to an empirical procedure, duplicate cells were measured under as varied conditions as possible, and in many instances entirely new gelatin solutions were made up. All measurements were carried out at 25°.

⁹ With considerations as noted before (see Ref. 5).

Results

The information given in Table III is typical of the results obtained with other cells. This table gives measurements with cells containing 0.874% of gelatin.

At the top of the table is indicated the type cell with the boundaries $E_1(\text{G})$, $E_2(\text{G})$ and $E_3(\text{G})$. Small arrows give the direction of flow of positive current in each boundary and a large arrow indicates the positive

or negative character of the entire cell; if from left to right the potential is considered to be positive and if from right to left negative. The first half of the table gives the measured values with Cell A and the second half those with Cell B. The first entry under "Time" gives the hour at which the cell was first placed in the thermostat bath. Successive entries give the time when measurements on the various boundaries were made. The readings in millivolts obtained with the three boundaries are given in the columns labeled $E_1(G)$, $E_2(G)$ and $E_3(G)$. In columns $E(G)$ and $E_s(G)$ are given the measured values for the total cell and also the values as determined from the algebraic sums of the boundaries.

It can be seen in both Cells A and B that in most instances the "time changes" in boundaries are very small, being of the order of a few tenths of a millivolt. The averages of the duplicate cells are very good.

Cells containing 0.437, 1.31, 1.75, 4.47, 8.74, 10.49, 12.23 and 17.48% of gelatin were treated in a manner similar to that illustrated in Table III.¹⁰

With higher concentrations of gelatin the "time changes" in boundaries $E_1(G)$ and $E_2(G)$ became more noticeable, although they consisted of fluctuations from hour to hour and did not show a general drift in any given direction. The 8.74% gelatin solutions became very viscous and overnight the gelatin in 0.01 *N* hydrochloric acid set to a gel. This had little effect on the boundary as comparison between readings taken at night and those taken the following morning showed only a change of 0.35 mv. and 0.20 mv. on two separate cells. With the 17.48% gelatin cells both gelatin solutions changed to gels within a few hours, but this change in state showed no noticeable effect on any of the potentials. In general, the agreement between duplicate cells and the deviations in readings in the single boundaries were not so good with the higher concentrations of gelatin, that is, above 10% of gelatin, but the potentials were perfectly definite. However, this irregularity at the higher concentrations introduced no difficulty since the significant conclusions are based upon results obtained at lower concentrations.

In practically every case values for duplicate cells agreed to less than 0.5 mv. and in most cases to within a few tenths of a millivolt. This shows that diffusion potentials with the supposedly complex gelatin systems are as accurately reproducible and as definite as with the simpler hydrochloric acid-sodium chloride systems.

In the cells containing more than 1.09% of gelatin, Boundary $E_3(G)$ showed a rather erratic behavior, the initial value for the boundary being much larger than any of the other values. This fall in potential amounted to as much as 10.7 mv. in ten hours. The reason for the apparent "time

¹⁰ The original thesis may be consulted for detailed measurements on these cells.

effect" in this boundary and others was made the subject of a special investigation and has been satisfactorily explained.

The graphical representation of the changes in diffusion potential in the different cells with the amount of gelatin added is given in Fig. 3, Curves $E_1(G)$, $E_2(G)$ and $E_3(G)$. In all instances the percentage of gelatin added to the solutions is plotted against the potential in millivolts.

Curve $E_1(G)$ shows the change in potential for Boundary $E_1(G)$ with increasing amounts of gelatin where x , the amount of gelatin in 100 cc. of solution, varies from 0.437 to 17.4 g. This potential starts at zero, since there is 0.10 *N* hydrochloric acid on each side of the boundary, increases gradually as gelatin is added to one side and finally reaches a maximum of +40 mv., when the gelatin concentration is about 10.9%. Beyond this concentration, as more gelatin is added, the potential remains practically constant in the region of +40 mv.

Curve $E_3(G)$ shows the changes in potential for Boundary $E_3(G)$. The potential starts at zero, since 0.01 *N* hydrochloric acid is on both sides of the boundary. As gelatin is added to one of these solutions, that is, as x varies from 0.437 to 17.4, the potential becomes increasingly more negative very rapidly, and soon reaches a limiting value of -31.50 mv. at 1.09% gelatin concentration. With higher concentrations of gelatin the potentials become largely indeterminate, although they tend to remain in the region of -31 mv.

Curve $E_2(G)$ represents Boundary $E_2(G)$, where x again varies from 0.437 to 17.4. The potential for this boundary starts with that between 0.10 *N* and 0.01 *N* hydrochloric acid, increases gradually as equal amounts of gelatin are added to both solutions and finally reaches a maximum of +54.97 mv. at a concentration of 1.09%. As more gelatin is added to both sides, that is, as x continues to increase, the potential drops rapidly, becomes negative and finally reaches a minimum of about -39 mv. It then remains constant for higher gelatin concentrations. The minimum point on the curve corresponds to a gelatin concentration of about 10.9%.

In Fig. 4 are given graphically the results with the hydrochloric acid-sodium chloride cells which have been previously described. The boundaries are indicated under each curve. The number of cc. of sodium hydroxide solution added to produce the hydrochloric acid-sodium chloride mixtures are plotted against the resulting potentials in millivolts.

Equivalent Weight of Gelatin from Diffusion-Potential Curves

If the curves for the hydrochloric acid-sodium chloride systems are compared with the curves for the hydrochloric acid-gelatin systems, it will be noted that their general appearance is strikingly similar. This would seem to indicate that the mechanism which is the cause of the

potentials in the hydrochloric acid-gelatin systems is perhaps similar to that of the hydrochloric acid-sodium chloride systems and interpretations that might be applied to the latter could also be applied to the former.

In the hydrochloric acid-sodium chloride curves, the maximum and minimum points on each curve correspond to the condition where complete

Fig. 4.—Diffusion potential changes with boundaries E_2 $(0.10 - x)$ N $HCl + x$ N $NaCl$ | $(0.1 - y)$ N $HCl + y$ N $NaCl$; E_3 $(0.01 - y)$ N $HCl + y$ N $NaCl$ | 0.010 N HCl ; E_1 0.10 N HCl | $(0.10 - x)$ N $HCl + x$ N $NaCl$.

combination between hydrochloric acid and sodium hydroxide has occurred. It seems clear from examination of the hydrochloric acid-gelatin curves that the four points of inflection on these three curves must indicate definite regions where complete combination between gelatin and hydrochloric acid has taken place. On both Curves $E_2(G)$ and $E_3(G)$ the first breaks occur at a gelatin concentration of 1.09%. This would correspond

to an equivalent weight of gelatin of 1090, since the solution at this point contains 1.09 g. of gelatin in 100 cc. of 0.10 *N* hydrochloric acid, and hence 1090 g. of gelatin would be necessary to combine with one equivalent weight of hydrochloric acid. On Curve $E_1(G)$ the first break and on Curve $E_2(G)$ the second break occur at a concentration of close to 10.9%, which corresponds to a condition where gelatin has combined with all the 0.10 *N* hydrochloric acid. This again gives the equivalent weight of gelatin as close to 1090.

These curves offer a striking proof that combination between gelatin and hydrochloric acid at concentrations ranging from 0.01 *N* to 0.10 *N* occurs in stoichiometric proportions, and the amount of gelatin which will combine with one equivalent weight of hydrochloric acid is 1090.

Other values which have been obtained for the equivalent weight of gelatin are given in a summarized form in Table IV. The results obtained in this work compare favorably with Hitchcock's values and also with those calculated by Greenberg and Schmidt.

Summary

1. A cell system is described which allows a close approximate measurement of diffusion potentials.

2. Reproducible diffusion potentials which show but small "time effects" have been measured with hydrochloric acid systems, hydrochloric acid-sodium chloride systems and hydrochloric acid-gelatin systems.

3. The reaction between hydrochloric acid and gelatin appears to be stoichiometric, purely chemical in nature.

4. A new and unusual method for determining the combining capacity of gelatin for hydrochloric acid is given. Four independent boundary measurements give the equivalent weight of gelatin as close to 1090.

Work of this nature is to be continued with di- and tri-basic acids and bases with gelatin, also for similar systems in which gelatin will be replaced by other proteins.

DIFFUSION-POTENTIAL MEASUREMENTS APPLIED TO HYDROCHLORIC ACID-GELATIN SYSTEMS. II. THE COMPONENTS OF HYDROCHLORIC ACID-GELATIN SOLUTIONS¹

BY EGBERT K. BACON WITH ALFRED L. FERGUSON

RECEIVED MAY 5, 1927

PUBLISHED AUGUST 5, 1927

A previous article² has shown that the equivalent weight of gelatin can be obtained from diffusion-potential measurements on hydrochloric acid-gelatin systems and that the reaction between hydrochloric acid and gelatin appears to be a stoichiometric one. This article explains the irregularities that were shown in some of the previous measurements³ and gives a more complete understanding of the conditions as existing in the various boundaries and solutions. All references to curves of Figs. 3 and 4 in this article refer to the same figures of the previous article.

The Effect of Uncombined Gelatin at the Diffusion Boundary

From comparison of curves in Fig. 3 with those in Fig. 4 it will be seen that the hydrochloric acid-gelatin solutions were not exactly similar to the hydrochloric acid-sodium chloride mixtures, as gelatin was added

¹ The material presented in this article is constructed from a portion of the thesis submitted to the Graduate School of the University of Michigan by Egbert K. Bacon, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

² Ferguson and Bacon, *THIS JOURNAL*, **49**, 1921 (1927).

³ Portions of Curve $E_3(G)$ were concave upward, while similar portions of Curve E_4 were concave downward. Large "time effects" were observed in certain regions of curves $E_1(G)$, $E_2(G)$ and $E_3(G)$.

to the hydrochloric acid without regard to the amount needed for complete combination. (In fact, this amount was not known until after the experiments were carried out and the equivalent weight was determined.) Thus it happened that in many cases there was uncombined gelatin present in the acid-gelatin mixtures.

With the hydrochloric acid-sodium chloride mixtures free sodium hydroxide was never present. If sodium hydroxide had been added to the 0.01 *N* hydrochloric acid after complete neutralization had occurred (which corresponds to the regions beyond the maximum point *b* on Curve E_2), the condition at the boundary would have been

At such a diffusion boundary there is a new source of potential, that between *x* *N* hydrochloric acid and *y* *N* sodium hydroxide which, according to Planck,⁴ would be largely indeterminate because chemical action between sodium hydroxide and hydrochloric acid takes place at the boundary.

This appears to be similar to the condition which resulted in the *b c* region of Curve $E_2(G)$. The point *b* on the curve corresponds to a condition of complete combination between gelatin and 0.01 *N* hydrochloric acid so that instead of writing the boundary as

a more exact condition is given as

Thus, there was free hydrochloric acid and uncombined gelatin in contact at the boundary, until complete combination between the 0.10 *N* hydrochloric acid and gelatin had occurred, that is, a concentration of 10.9% of gelatin.

"Corrected" Curve for Boundary $E_2(G)$

If the above is the explanation of the real conditions existing at the contact boundary in the region *b c* of Curve $E_2(G)$, then a boundary such as

should correspond more nearly to the condition of the same region on curve E_2 of the hydrochloric acid-sodium chloride system,

Accordingly, boundaries such as that given in (4) were measured. The results of these "corrected" measurements are given in Fig. 1 A, corresponding to 1.75, 4.37, 8.74 and 10.49% gelatin.

The path of the curve *b'c'* between 1.09% of gelatin and 10.9% of gelatin is now concave downward, the same as in Curve E_2 . It converges to the same point *c'*, as does Curve $E_2(G)$, when complete combination

⁴ Planck, *Wied. Ann.*, **40**, 561 (1890).

between 0.10 *N* hydrochloric acid and gelatin has taken place (10.9% of gelatin). This is further proof that the equivalent weight of gelatin is close to 1090, as shown in the previous article.

To show that uncombined gelatin present in the left-hand side of the boundary would have no appreciable effect on the potential after all of the free hydrochloric acid had combined with the gelatin, a boundary of the following type was measured.

This should give a potential similar to a boundary such as

since there is no free hydrochloric acid present in either system, but only combined and uncombined gelatin.

Fig. 1A.— $E_2(G)$, $0.01 \text{ } N \text{ HCl} + x\% \text{ gelatin} \mid 0.01 \text{ } N \text{ HCl} + y\% \text{ gelatin}$, where x varies from 0 to 10.9 and y varies from 0 to 1.09.

The potentials of these two boundaries were -37.69 mv. and -39.79 mv. , respectively. This close agreement shows that an excess of gelatin beyond the amount required for complete combination with the acid present has no appreciable influence on the diffusion potential.

The Function of Free Hydrochloric Acid and Uncombined Gelatin at the Diffusion Boundary

From these considerations it seems clear that the difference in observed potentials, as shown by Curves $E_2(G)$ and $2E_2(G)$, between points b

and c and b' and c' is a function of the concentration of free hydrochloric acid on one side of the boundary and the concentration of the uncombined gelatin on the other. It is the presence of these components on opposite sides of the contact layer that is the cause of the differences in diffusion potentials.

This is illustrated more conclusively by the following considerations. Any point on the $b'c'$ region of Curve $2E_2(G)$ represents the boundary condition as

$$(0.10 - x) \text{ N HCl, } y \% \text{ combined gel. } | 0.01 \text{ N combined gel.} \quad (8)$$

If z per cent. of iso-electric gelatin were added to the 0.01 N combined gelatin, any change resulting in the diffusion potential would be caused by the effect produced by the introduction of this excess of iso-electric gelatin. This is exactly the conditions that are represented in the region $b c$ of Curve $E_2(G)$, only it gives the results of proportionally increasing amounts of uncombined gelatin in contact with decreasing amounts of hydrochloric acid. If one of these factors is kept constant, the effect produced by changing quantities of the other can be observed. A boundary of the type

$$0.10 \text{ N HCl, } 1.75\% \text{ gel. } | 0.01 \text{ N combined gel., } x\% \text{ uncombined gel.} \quad (9)$$

illustrates such a condition. Boundaries of this nature were measured.

The solution in the left-hand side contained 1.75% of gelatin in 0.10 N hydrochloric acid or 0.084 N hydrochloric acid plus combined gelatin. The composition of this solution was kept constant. Varying quantities of iso-electric gelatin (which remained in the uncombined state) were added to the combined gelatin solution on the other side of the boundary.

The results of these measurements are given graphically in Fig. 2A, Curve 2(G)A. The potential is plotted as a function of the value of x , and the values of x used are 0, 0.66, 1.53, 4.15, 5.03 and 11.25. The curve appears to reach a limiting value at a potential around +15 mv. Concentrations of gelatin beyond 5 or 6% produce little effect.

Curve 2(G)B represents a boundary of the type

$$0.10 \text{ N HCl, } 5.24\% \text{ gel. } | 0.01 \text{ N combined gel., } x\% \text{ uncombined gel.} \quad (10)$$

This is similar to Boundary 9 but represents a lower starting point on $b'c'$, that is, where the free hydrochloric acid on the left-hand side of the boundary has the lower concentration, 0.052. The values for x are 0, 4.15 and 5.9. Concentrations of gelatin beyond 4% show little effect on this boundary.

Curve 2(G)C shows the results when the free acid has the still lower concentration, 0.0084 N . Constancy in potential is reached between 1 and 2% of gelatin.

Curve 2(G)D shows a condition of constancy when there is no free hydrochloric acid left. Any concentration of gelatin now has no appreciable effect on the potential.

To show further the difference between the effect of combined and uncombined gelatin the following boundary was measured,

$$0.10 \text{ N HCl, } 1.74\% \text{ gel.} \mid 4.37\% \text{ solution combined gel.} \quad (11)$$

in which one solution represents 1.75% of gelatin in 0.10 N hydrochloric acid and the other a 4.37% solution of *combined* gelatin, based upon the combining weight 1090 for gelatin. The value -39.19 mv. was obtained for the potential of this boundary. A similar boundary which contained 4.37% of *iso-electric* gelatin in 0.01 N hydrochloric acid gave a value of -8.61 mv.

Fig. 2A.—The influence on diffusion potentials when uncombined gelatin is on one side of the boundary and free HCl on the other. Curve A, 1.7% gelatin, 0.084 N HCl; B, 5.2% gelatin, 0.052 N HCl; C, 10% gelatin, 0.008 N HCl; D, 10.9% gelatin, 0.000 N HCl.

Conclusions

The importance of defining hydrochloric acid-gelatin solutions in terms of free acid, combined and uncombined gelatin, is shown in these experiments. This can be done only if the stoichiometric character of the gelatin-acid combination is admitted and the equivalent weight of gelatin known. The understanding of the conditions existing in these hydrochloric acid-gelatin solutions and the cause of the observed potentials become clear when the following assumptions are made.⁵

- (1) Iso-electric gelatin combines stoichiometrically with hydrochloric

⁵ These are essentially the same as those of Loeb and his co-workers.

acid, at least between concentrations of 0.10 *N* and 0.01 *N*. Other interpretations of the curves which have been discussed could hardly lead to other conclusions. Five independent boundary measurements establish the equivalent weight of gelatin as close to 1090.

(2) Iso-electric gelatin, although considered neutral, is able by its amphoteric character to combine with hydrochloric acid much in the same manner as hydrochloric acid combines with sodium hydroxide. A highly ionized salt, gelatin chloride, is formed which is dissociated into a gelatin cation and a chloride anion.

From a consideration of these assumptions the diffusion potentials of hydrochloric acid-gelatin systems become understandable. When the components of the solutions are gelatin chloride (combined gelatin) and free hydrochloric acid, the observed potentials are very much the same as if the components were hydrochloric acid and sodium chloride. The introduction of any uncombined gelatin at one of the diffusion boundaries where free hydrochloric acid is present results in interaction between hydrochloric acid and gelatin at the boundary layer, with the formation of gelatin chloride. Thus the diffusion layer would be largely indeterminate and the potential would have no specific value or precise meaning. Examination of the experimental data and curves prove this, as erratic results were obtained whenever free hydrochloric acid and uncombined gelatin were at the boundary. This is in accord with Planck's views that a diffusion potential which results at a boundary where there is chemical action is largely indeterminate.

Summary

Important conclusions resulting from this investigation may be summarized as follows:

1. The components of hydrochloric acid-gelatin solutions should be defined in terms of free acid, combined and uncombined gelatin.
2. Diffusion potentials of hydrochloric acid-gelatin systems are only understandable if the hydrogen chloride-gelatin combination results in the formation of highly-ionized gelatin chloride.

A NEW TYPE OF ROTATING ADIABATIC CALORIMETER. - THE SURFACE ENERGY AND HEAT OF SOLUTION OF SODIUM CHLORIDE. II

By S. G. LIPSETT, F. M. G. JOHNSON, AND O. MAASS

RECEIVED MAY 6, 1927

PUBLISHED AUGUST 5, 1927

In a previous paper¹ a method was described for determining the surface energy of a solid by measurement of the difference between the heat of solution of the solid in a coarsely crystalline and in a finely divided condition. The calorimeter used for this purpose had a rather serious defect in that the salt was exposed to the action of water vapor before solution was effected. A modified form of this calorimeter was therefore constructed, in which this defect was remedied; and in this paper an account of the work done with this calorimeter will be described. The heat of solution of finely divided sodium chloride has been again determined, this time directly; the results substantiate those obtained before. The area of the finely divided salt has been measured with more precision by the use of two different methods, and a more accurate value for the surface energy of solid sodium chloride thereby attained. With this calorimeter the heat of solution of the coarsely crystalline sodium chloride has been determined at 20° over the whole range of concentrations. Comparative agreement between duplicate experiments was obtained to better than 0.05% for concentrations above 10%. The heats of solution at 25° determined in the previous paper were corroborated, and from the temperature coefficient of the heats of solution the specific heats of sodium chloride solutions were calculated with high accuracy.

The main features of the former calorimetric apparatus are embodied in the present form and their description will not be repeated here. For a complete description of the apparatus, method of procedure, the precautions and corrections necessary, etc., the reader is referred to the first paper. The silver calorimeter vessel was, however, completely remodeled, and its description follows.

Description of Calorimeter

The calorimeter (Fig. 1) was a rotating type, cylindrical in shape and of the same exterior dimensions as the previously used calorimeter, so that it could be substituted in place of the old calorimeter and used with the same copper jacket, radiation thermel and axle as before. It differed in this respect, that the salt was placed in a separate receptacle which was covered by a lid so that the salt was protected from water vapor. For proper manipulation it was found necessary to be able to remove

¹ Lipsett, Johnson and Maass, *THIS JOURNAL*, 49, 925 (1927).

this receptacle from the calorimeter and for this purpose one end of the calorimeter was made removable.

As before, the calorimeter was constructed of sterling silver sheet. The open end of the calorimeter was flanged with a rim A of silver 3 mm. thick. This was closed by a disk of silver sheet B, which carried the supporting axle. A stout ring of brass C was made to press the silver disk tightly against the flange by means of ten brass screws running into the flange. The flange was previously coated with a thin film of vaseline. This gave a water-tight seal which was never found to give trouble and which allowed the easy introduction and removal of the box, D, which contained the salt. This box is shown separately in Fig. 1, c and d as it appears when removed from the body of the calorimeter. To enable it to be inserted into the calorimeter without jarring, and to hold it in position once inserted, a "runway" was constructed inside the calorimeter.

Fig. 1.

This was made of the same material as the rest of the calorimeter but is shaded in the diagram to differentiate it from the box. It consisted of two silver bars, E, soldered at each end to vertical pieces of silver sheet, which were in turn soldered to the wall of the calorimeter. The vertical sheet near the closed end of the calorimeter contained a slot into which fitted a projection F from one end of the box, while the other vertical sheet bore a small threaded rod which fitted into a hole in a projection G at the other end of the box. A small nut on the threaded rod served to hold the box in position. The top of the box was flanged and ground plane. A single piece of silver, $62 \times 11 \times 1.7$ mm., ground plane on one side, served as a lid. On rotating the calorimeter, the lid fell off and solution of the salt took place as before. To give an air-tight seal between the lid and the box, the flange of the box was coated with Glycoline. A film of vaseline, although preferable as a seal, caused the lid to adhere so strongly that it did not fall off on rotation. Even with glycoline, a lighter lid did not fall off on rotation.

It was found that if the lid were left free to slide about at random in the box during rotation, a rather large amount of heat was generated by friction, enough to cause a rise in the temperature of the calorimeter, containing 50 cc. of water, of about 0.0005° per minute. Small projections H were, therefore, soldered to the box, which trapped the lid after the first revolution of the calorimeter and prevented it from moving about

subsequently. The direction of rotation is indicated by the arrow in the diagram and the position of the trapped lid is shown at J. The lid, when so caught, acted as a baffle plate and caused more efficient mixing during the rotation, with the development by friction of only one-third of the heat generated when the lid was free to move about.

It will be noticed that the box is situated a little to one side in the calorimeter. This enabled a large quantity of water to wash in and out of the box on each revolution, thus increasing the speed of mixing.

The opening, K, for the water was so placed that there was no risk of wetting the lid of the box when the water was introduced. A silver plug closed this opening, as before.¹ The supporting axles, I, and M, were constructed similarly to those in the previous calorimeter.

Other Parts of the Apparatus

Only one change was made in the remainder of the apparatus. This consisted in the addition of a small tube from the copper jacket to the atmosphere, which enabled the air in the space between the calorimeter and the surrounding jacket to be kept at atmospheric pressure. Previously, the only tubes leading from the jacket to the outside were the tube containing the thermel lead wires and the tube through which the axle passed. The former was impervious to the passage of air since it had been filled with paraffin wax. The latter was found to be air-tight when the calorimeter was at rest, the vaseline used as lubricant acting as a seal, but on rotation the movement of the axle apparently offered means for the slow passage of air. This affected the calorimetric determinations in the following way. The temperature of the room might be, say 15° when the calorimeter was put in position and the outer jacket clamped on. If the calorimeter were later warmed to 25°, the air enclosed in the air gap would exert a pressure slightly higher than atmospheric but would not be able to expand. When the calorimeter was rotated, however, it would be able to escape and its expansion would produce a cooling effect. To prevent this, the air in the air gap was, therefore, opened to the atmosphere after the calorimeter had been brought to the temperature at which the run was to be made.

Procedure

A weighed quantity of salt was put into the box, the flange of the box was covered with a film of glycoline, and the box and contents were then allowed to stand in a desiccator over phosphorus pentoxide for two hours. The lid was put on the box while it was still enclosed in the desiccator, so that the box was filled with perfectly dry air. The box was then slipped into the calorimeter, the flange of the calorimeter was coated with vaseline, the end screwed on and a weighed amount of water run in. The procedure then followed the same course as described for the previous calorimeter.

Corrections

The corrections applied were the same as those used previously, with two additions. A correction was made for the heat capacity of the gly-

coline and the vaseline. The amounts of these substances used were practically the same in all the experiments, namely, 0.016 g. of glycoline and 0.035 g. of vaseline for which a total heat capacity was estimated of 0.02 cal.

The other correction necessary was due to the evaporation of water vapor into the dry air of the box when the lid fell off on rotation. This correction became large when only a small amount of salt was present in the box and was one of the chief reasons for making the box as small as possible. As a check on this correction, a blank run was carried out without using any salt, but filling the box with dry air as in the regular procedure and using 50 cc. of water in the calorimeter. On rotation a cooling effect was observed which, after allowing for heat generated by friction, amounted to 0.0030° . The theoretical lowering, as calculated, was 0.0029° .

The specific heat of the brass (64% copper, 36% zinc) used for parts of the calorimeter was taken as 0.0907 at 25° .² The weight of the brass parts was 20.39 g. The total weight of the sterling silver which made up the calorimeter was 133.94 g. Its specific heat was taken as 0.0581, as before.

Heats of Dilution.—It is obvious that this type of calorimeter can be used in determining heats of dilution as well as heats of solution. To illustrate this, some determinations were carried out with very dilute solutions of sodium chloride.

At 25° , 8.2 cc. of a 1.0% solution was placed in the small box and 41.3 cc. of water outside. On dilution, a rise in temperature of 0.0016° was obtained, of which 0.0011° was due to heat generated by friction during the rotation, leaving 0.0005° as the rise in temperature due to the reaction itself. To show the accuracy possible in measuring such small changes in temperature, the rise in temperature due to rotation was determined three times in this experiment, giving the values 0.0012, 0.0010 and 0.0011° .

Other heats of dilution were determined at 20° .

Comparison with Previous Results.—As a check on the apparatus and the previous work, some of the former determinations were repeated. Two runs were made with coarse salt at 25° . For a final concentration of 5.670%, the heat of solution was found to be -896.3 cal. per mole, as compared with -895.8 cal. found before. For a 4.620% solution, -928.1 cal. per mole was obtained as compared with -927.6 obtained previously. To substantiate the maximum in the heat of solution curve at 1%, a 1% solution was diluted to 0.166% and as was expected heat was evolved on dilution, giving $+23$ cal. per mole as the heat of dilution. As was just shown, the change in temperature on this dilution is very small and the

² Doerincel and Werner, *Z. anorg. allgem. Chem.*, 115, 1 (1921).

error in this heat of dilution may be 8 cal. per mole. In the previous work the heat of solution for a 1% solution was found to be -1015 cal. per mole, which gives -992 cal. per mole as the heat of solution for a 0.166% solution.

A determination was also made with some of the finely divided sublimed salt which had been used in the previous work. Its heat of solution was found to be 12.1 cal. per mole less than that of the coarse salt. The indirect measurements used previously gave a difference of 12.3 cal.

Heats of Solution of Sodium Chloride at 20°.—The results obtained for the heats of solution of sodium chloride at 20° are given in Table I.

The specific heats in Col. 2 were obtained from the same sources as in the previous paper. The calorie used throughout this paper is the 18° calorie and is taken equivalent to 4.1825 joules. Col. 3 gives the weight of water in which the salt was dissolved. The value for the 0.22% solution was obtained by diluting a 1.20% solution to 0.22%. For concentrations above 10%, the agreement between duplicate experiments is better than 0.05%, while for more dilute solutions, the agreement is of necessity not so exact.

The Specific Heats of Sodium Chloride Solutions.—The specific heat of a solution can be calculated very accurately from a knowledge of the temperature coefficient of the heat of solution, provided the specific heats of the pure solute and solvent are known. This is a direct application of the well-known Kirchhoff's Law, namely,

$$C - C^1 = (U^1 - U)/\Delta\theta \quad (1)$$

In this equation U represents the heat of reaction at θ° , U^1 , the heat of reaction at $(\theta + \Delta\theta)^\circ$, and C and C^1 represent the mean molal heat

capacities, respectively, of the reacting substances and of the products between the temperatures Θ and $(\Theta + \Delta\Theta)$.

In the present case, this equation may be written in the following form.

$$C_A + C_B - C_S = \Delta U/5 \quad (2)$$

C_A is the heat capacity of one mole of sodium chloride solid at 22.5° ; C_B is the heat capacity at 22.5° of the water in which it is dissolved, and C_S is the total heat capacity of the resulting solution, also at 22.5° . ΔU is the difference between the molal heats of solution at 25 and 20° .

The value for ΔU (disregarding all previous values used for the specific heats of sodium chloride solutions) may be expressed in terms of C_S and the actual experimental data obtained in determining the heats of solution at the two temperatures concerned. Knowing the values of C_A and C_B , the equation may be solved for C_S and the specific heat of solution thereby obtained. The details of such a calculation will not be given here since this method of obtaining specific heats has been described in detail by Richards and Rowe,³ who determined the specific heats of solutions from the temperature coefficient of the heats of dilution.

This calculation, although quite straightforward, is somewhat tedious in execution and the procedure, in the present case, was considerably simplified by obtaining the values for ΔU directly by difference from the heats of solution at 25 and 20° as already determined in this work. Although the calculation of these heats of solution involved the use of specific heats of the solutions as available in the literature, yet it will be seen that a fairly large error (say 0.3%) in these specific heats, although leading to an equal error (0.3%) in the heats of solution at 25 and 20° and thereby producing the same error in the value of ΔU , will finally lead to a much smaller error (less than 0.01%) in the specific heat of the solution then calculated according to Equation 2. If the calculated specific heat, thus found, differs by more than 0.3% from the value in the literature, the former may then be used to recalculate ΔU , and this, in turn, will give a more accurate value for the specific heat. In the present case, the values for the specific heats of sodium chloride solutions in the literature were found to be sufficiently accurate for the purpose, and the values of ΔU obtained by their use were used to calculate C_S . The mode of calculation is illustrated by the following example.

The specific heat of a 4.62% solution was taken as 0.9444 at 22.5° .^{3b} The molal heat of solution of sodium chloride at this concentration was found to be -928.1 cal. at 25° , and -1043.2 cal. at 20° . Substituting in Equation 2, the following result is obtained.

$$(0.208)(58.45) + (0.9993)(1206.7) - C_S = (1043.2 - 928.1)/5$$

or

$$12.16 + 1205.86 - C_S = 23.02$$

whence

$$C_S = 1195.0$$

³ (a) Richards and Rowe, *THIS JOURNAL*, **42**, 1621 (1920); (b) **43**, 770 (1921).

The first term represents the specific heat of solid sodium chloride at 22.5° multiplied by its molecular weight. It will be seen that an error of 1% in this heat capacity would lead, in this instance, to an error of only 0.01% in the value of C_S . The second term represents the specific heat of water at 22.5° multiplied by the weight of water in which the mole of salt was dissolved. This term is by far the largest of the three which result in the value of C_S and it is the most accurately known. The accuracy with which C_S may be determined is, therefore, limited by the accuracy with which the specific heat of water is known. The term on the right-hand side of the equation is $\Delta U/5$, and it is evident that an error of 1% in the evaluation of ΔU will result in an error of only 0.02% in the value for C_S . The weight of solution formed on solution of one mole of salt is 1265.2 g. which gives 0.9445 as the specific heat of the solution at 22.5° . The above analysis is given in detail to show that this method of determining specific heats, although indirect, is yet capable of yielding results of high accuracy.

The specific heats of sodium chloride solutions were then calculated according to the following procedure. The heats of solution at 25° and at 20° , obtained previously, were used, and values for ΔU were obtained by difference. Following the method suggested by Richards and Rowe, the values for ΔU were plotted against concentration and a smooth curve was drawn through the points. From the curve the values of ΔU at round concentrations were obtained and from these the specific heats of solutions at 22.5° were calculated, using Equation 2. The change in the specific heats with temperature was estimated from results given by Bousfield and Bousfield⁴ and the specific heats at 20° and at 25° thereby calculated. The specific heats so obtained are possibly accurate to 0.05%. The previous values for the heats of solution have all been recalculated, using these specific heats, since it was thought that more reliance could be placed on the newer values than on some of the older ones. In view of the increased accuracy afforded by these results, a more careful calibration of the platinum-resistance thermometer was made and showed that the previous results were 0.06% too low. The results were, therefore, increased by this amount. The heats of solution so obtained were plotted against concentration and the values at round concentrations found from the curve. These values, together with the values for the specific heats of the solution, as calculated from the temperature coefficient of the reaction, are given in Table II.

Among the most accurate determinations previously made of the specific heats of sodium chloride solutions are those by Richards and Gucker,⁵ and Richards and Rowe^{3b} at 18° . In Table III, their results

The Heat of Solution of Finely Divided Sodium Chloride

Preparation of the Finely Divided Salt.—The salt was prepared by sublimation as before, but a new settling box was used (Fig. 2).

The dimensions of this box were 20 × 20 × 210 cm. It was divided into eleven compartments by baffle plates, as shown. These compartments gradually increased in size. The first, where the salt entered, was 5 cm. and the last 35.5 cm. long. The salt was sublimed from the platinum retort and the vapors were blown through this box. The coarser particles settled out in the first compartments and only the finest reached the last compartments. Glass plates on the bottom of each chamber received the salt as it fell, very little adhering to the walls. The front of the box, a glass plate, was removable. Strips of rubber (shaded in the diagram) were glued around the open

side of the box and down the edge of each baffle plate, and the glass was pressed against this by means of a wooden framework which was bolted to the box as shown.

Measurement of Size.—The size of the salt particles was obtained by two methods. In the first, the diameter of the particles was measured directly by the use of photomicrographs.⁶ In the second, the number of particles in a given weight of salt was found by direct count using a hemacytometer.⁷ In the latter procedure redistilled turpentine was used as a dispersion medium. Since the particles were not all of the same size, the relative distribution of the particles with regard to size was obtained from the photomicrographic measurements, and this, combined with the number of particles in a given weight, gave the average diameter per particle. The two methods gave results agreeing to within 0.1μ in the diameter of the average particle.

Fig. 2.

The Surface Energy of Solid Sodium Chloride

The heat of solution of the finely divided salt was measured at a concentration of 4.62% at 25°. The area of the salt was measured in the manner just indicated and the surface energy then calculated. The results are given in Table IV.

TABLE IV
SURFACE ENERGY OF SOLID SODIUM CHLORIDE AT 25°

Diameter of av. particle, ^a μ	Area per mole, sq. cm. $\times 10^{-8}$	Surface energy per mole, cal.	Surface energy per sq. cm., ergs.
1.00	1.62	15.3	395
1.16	1.40	13.6	406
1.14	1.42	12.1	356

^a This is not the arithmetical mean of the measured diameters but is a diameter such that, if the salt were composed of particles equal in size, which had this diameter, the area per mole would be the same as that actually occurring.

The figures in Col. 3 are the experimentally determined differences between the heat of solution of the coarse salt and the finely divided salt. The mean value for the surface energy of solid sodium chloride, as given above, is 386 ergs per sq. cm. at 25°.

Summary

1. An improved type of rotating adiabatic calorimeter is described with which heats of solution or heats of dilution may be determined with high accuracy using only small quantities of material. The apparatus is constructed so that the solute, before solution, is not exposed to the vapor of the solvent.

2. Heats of solution of sodium chloride were determined at 20° over the whole range of concentrations.

3. An indirect but accurate method of determining specific heats of solutions is described, in which the specific heats are calculated from the temperature coefficient of the heats of solution.

4. From the heats of solution of sodium chloride at 20°, and those determined previously at 25°, the specific heats of sodium chloride solutions were calculated with an accuracy perhaps of 0.05% over the whole range of concentrations.

5. The heat of solution of finely divided sodium chloride was determined directly and from the difference between its heat of solution and that of the coarse salt, the surface energy of solid sodium chloride was calculated.

THE ADSORPTION OF MERCURY VAPOR BY CHARCOAL

BY ALBERT SPRAGUE COOLIDGE

RECEIVED MAY 25, 1927

PUBLISHED AUGUST 5, 1927

In most arrangements for measuring gas adsorption, the adsorbent is constantly exposed to the vapor of mercury in pumps, manometers, etc., but it is tacitly assumed that no mercury is adsorbed. Sufficient grounds for this assumption are not evident. In general, vapors are more copiously adsorbed, the smaller the vapor pressures and molecular volumes of their liquids, the latter influence being particularly strong when the vapor is nearly saturated. On this basis, one would predict that mercury vapor would be more readily adsorbed than any other vapor or gas usually present, and that in the presence of liquid mercury at the same temperature, a sample of ordinary activated charcoal would take up several times its own weight. It is true that the pressure of mercury vapor in the system is generally very low; but this would merely delay, not prevent, adsorption, and in the course of a prolonged experiment there would be opportunity for considerable quantities of mercury to reach the adsorbent.

Certainly no such great adsorption occurs, and this is intimately connected with the fact that mercury does not wet charcoal. This means not that there is no attraction of the carbon surface for mercury atoms, but that this attraction is less than that of the free mercury surface, so that

the transfer of mercury from liquid to charcoal is endothermic. It should therefore occur, if at all, at high temperatures.

A preliminary investigation was made to see whether any adsorption could be detected at high temperatures. Three and five-tenths g. of activated coconut charcoal was suspended from a McBain¹ quartz spring balance, which had at 100° a sensibility of 5.45 mm. per g., and could be read, under the given conditions, to ± 0.005 mm., or about 0.3 mg. per g. of charcoal. At the higher temperatures used, the elasticity of the spring may have slightly increased, but the results did not seem to be sufficiently precise to make necessary the determination of a correction for this effect. Spring and load were hung in a wide glass tube closed at the top and connected at the bottom to a narrow vertical tube through which the system could be exhausted or mercury introduced from a leveling bulb. The wide tube and part of the narrow tube were kept at the desired temperature either by a vapor-bath (100, 218 and 306°) or by an electric furnace. The temperature of the latter was 480° as indicated by a pyrometer in which not much confidence was placed, although it was calibrated and found correct at 445°. A sharp temperature gradient thus existed in the narrow tube where it emerged from bath or furnace. In working at the higher temperatures, mercury was allowed to run in slowly until the meniscus reached a temperature at which the pressure of its vapor just balanced that due to the height of the leveling bulb. The pressure was estimated from the difference in levels, neglecting the expansion of the short column of heated mercury. It was found that the extension of the spring was proportional to the pressure, within the limits of error, showing that Henry's law holds, and that equilibrium was practically instantaneous. At the lower temperatures the pressure could not be safely found by this means; mercury was therefore allowed to enter the wide tube, and the pressure taken equal to the vapor pressure of mercury at the given temperature. No test of Henry's law could be made.

¹ McBain and Bakr, *THIS JOURNAL*, 48, 690 (1926).

The experimental results are displayed in Table I. Col. 3 shows the amounts adsorbed, in milligrams per gram of charcoal; Col. 4 gives the ratio of pressure to amount adsorbed. Assuming Henry's law to be valid at all temperatures, this may also be regarded as the isostere for a constant concentration of 1 mg. per g. of charcoal.

In Fig. 1, the logarithms of the average values of P/a are plotted in the usual manner against the reciprocal temperatures, and fall as well as could be expected upon a straight line, the 1 mg. isostere. On the basis of Henry's law, other isosteres have been calculated and plotted, as well as the vapor pressure of liquid mercury. The slope of the isosteres leads

Fig. 1.

to a calculated heat of adsorption of 8900 calories per mole, which is much less than the heat of evaporation, 13,000 calories. While the transfer of mercury from gas phase at constant pressure to charcoal is exothermic and favored by low temperature, the transfer from liquid mercury to charcoal is seen to be indeed endothermic, consuming some 4000 calories, and taking place more readily at higher temperatures. The situation is similar to that which I found to exist in the case of ice and charcoal,² and is precisely analogous to the retrograde solubility of certain liquid pairs. It does not appear to have been previously described in the case of the adsorption of the vapor of a liquid.

If charcoal adsorbing a certain quantity of mercury is cooled, the vapor pressure of liquid mercury at the same temperature will fall faster than

² Coolidge, *THIS JOURNAL*, 49, 708 (1927).

the equilibrium pressure of the given mixture, and at a certain temperature will overtake it; at this temperature the system will be saturated, that is, in equilibrium with liquid mercury. The relation between this temperature and the amount adsorbed is shown in Table II (still assuming Henry's law). If the system is further cooled, its equilibrium pressure, though diminished, will now exceed the vapor pressure of the liquid, so that mercury will be desorbed and will collect as free liquid. The values in Table II therefore represent the maximum possible adsorption at the given temperatures. Evidently, there will be no significant adsorption under the conditions usually prevalent in work on other gases.

TABLE II
MAXIMUM ADSORPTION OF MERCURY VAPOR

Temp., °C.	Vap. press. of liq. Hg, mm.	P/a	α_{\max} mg. per g.	Temp., °C.	Vap. press. of liq. Hg, mm.	P/a	α_{\max} mg. per g.
20	0.0013	0.0042	0.3	220	33.7	2.04	16
60	.03	.026	1.2	260	98	4.0	24
100	.28	.11	2.5	400	246	7.2	34
140	1.85	.35	5.3	360	790	11.5	69
180	9.2	.89	10				

The heat of adsorption of mercury vapor, although less than its heat of evaporation, is still greater than the heat of adsorption of many true gases, and mercury vapor might therefore well be able to displace such gases from charcoal. This may be the explanation of a phenomenon which was repeatedly observed. When coconut charcoal which had been only briefly evacuated was treated with mercury vapor for three minutes, a considerable quantity of permanent gas was found in the system after all of the mercury had been condensed out. The same effect was obtained with sugar charcoal which had adsorbed formic acid, and had been only briefly evacuated. In this case the gas was doubtless carbon monoxide. The amount of gas evolved was much greater than would have come off spontaneously in a vacuum in the same time. In both cases the effect ceased when the charcoal had been subjected to prolonged evacuation.

Summary

Charcoal has been found to adsorb small amounts of mercury vapor at high temperatures. The amount adsorbed decreases with rising temperature when the vapor is kept at constant pressure, but increases with rising temperature when the vapor is kept saturated. The heat of adsorption is smaller than the heat of evaporation. At room temperature the adsorption is negligible.

A NEW ABSOLUTE MANOMETER FOR LOW PRESSURES

BY WORTH H. RODEBUSH AND CURTIS C. COONS

RECEIVED JUNE 16, 1927

PUBLISHED AUGUST 5, 1927

The mercury manometer, including its more refined form, the McLeod gage, is preëminently the best type of manometer for measuring pressures below one atmosphere. It cannot be used, however, with gases which react with or dissolve appreciably in mercury, nor with gases which condense at the temperature at which the manometer is maintained, and the temperature range of operation is limited by the physical properties of mercury. The glass diaphragm manometer as developed by Daniels¹ and others is highly satisfactory at pressures above 10 mm. and such a manometer has recently been used in this Laboratory with success at 300°. In order to secure accuracy at low pressures, however, the glass diaphragm must be made so thin that it is too fragile for practical use. Various other ingenious forms of manometers have been devised, such as the Knudsen gage, Pirani gage and numerous types of ionization gages.² They all appear to be unsatisfactory, however, in that they are either difficult to operate or that they are not absolute but must be calibrated for each particular gas, which means that some other manometer must be used ultimately.

In connection with problems in this Laboratory, a manometer was needed which could be used for the measurement of very low vapor pressures of substances at any temperature and also for the measurement of thermal transpiration effects at low pressures. Such a manometer has been developed. It is essentially an absolute manometer which can be constructed of a single material resistant to corrosive gases (for example, Pyrex or silica glass) and which can be used at any temperature that the material will withstand. The pressure range is substantially that of the McLeod gage.

The construction of the manometer is shown in Fig. 1. D is a disk of graphite, the lower surface of which is ground to seat on the ground end of the glass tube. B is a small bob of soft iron, enclosed in glass, and A is an

Fig. 1.

arm made from a quartz fiber by which the system is suspended. C is a coil through which a current is passed to bring an electromagnetic traction on B. When the disk is seated on the tube at low pressures the leakage is slight and a nearly perfect vacuum may be maintained in the tube E while pressure equilibrium is attained above.

In operation sufficient current is passed through the coil to seat the disk firmly on E and time is allowed for pressure equilibrium to be established.

Fig. 2.

The current is decreased until the disk rises from its seat on the end of the tube. At this point the apparatus functions as an electromagnetic balance. The upward pull of the bent arm A is equal to the weight of the system plus the pressure of the gas plus the electromagnetic force. The current at which the disk begins to rise from its seat is easily determined because as soon as the disk rises slightly the gas flows into E and the pressure is equalized above and below the disk so that what is observed is a sudden rise of the disk to a height of nearly a millimeter above its seat. It was feared that irregularities in the seating of the disk or sticking might cause irregular behavior but no such difficulty was experienced. The current value for the balance at a given pressure is highly reproducible.

The disk D as constructed has an area of about 3 cm², and a pressure of 0.01 mm. exerts a downward pull of about 40 mg. so that it is not difficult to get sufficient sensitivity. While the manometer can be calibrated ab-

solutely by loading the disk with weights, it is more convenient to check it against a McLeod gage using air in the apparatus. The calibration curve is shown in Fig. 2. The curve is nearly linear but there are several effects which might cause a slight curvature.

For use at higher temperatures a furnace is placed around the tube in the neighborhood of D. For some purposes it may be desirable to interchange the connections to pressure and vacuum and invert the disk D and its seat.

The "zero point" of the apparatus will change somewhat with temperature but it can always be checked against a vacuum. The manometer is, of course, not suitable for use where the escape of gas from the apparatus must be avoided.

THE COMPRESSIBILITY ISOTHERMS OF HYDROGEN, NITROGEN AND MIXTURES OF THESE GASES AT 0° AND PRESSURES TO 1000 ATMOSPHERES.

A CORRECTION

BY EDWARD P. BARTLETT

RECEIVED JUNE 17, 1927

PUBLISHED AUGUST 5, 1927

A gage of the dead-weight type was used in the determination of the pressures recorded in a recent publication¹ concerning the compressibility of hydrogen, nitrogen and their mixtures.

An accurate calibration of the gage, made possible through recent acquisition of new equipment, shows that it was correct to within 0.1% at pressures to 100 atmospheres. At pressures of 200 atmospheres and above, an unsuspected error has been introduced, through the use of an incorrect ratio for the multiplying power of a lever attached to the gage only at these higher pressures. The maximum error in published results is 0.62% at 200 atmospheres, and becomes less at higher pressures.

The corrected results follow. The table number refers to the corresponding table in the original paper.

At pressures to 100 atmospheres the corrected results agree with those of Holborn and Verschoyle to within a maximum difference of 0.26% in the case of pure hydrogen and within 0.11% in the case of pure nitrogen. At 200 atmospheres the agreement with Amagat's results is almost exact. The maximum deviation from Amagat's results above 200 atmospheres is 0.34%. Corrected results for the three gas mixtures agree with those of Verschoyle at pressures to 100 atmospheres to within 0.10%. At 200 atmospheres the later results are larger by a maximum of 0.4%.

CALCIUM NITRATE. I. THE TEMPERATURE-COMPOSITION RELATIONS OF THE BINARY SYSTEM CALCIUM NITRATE-WATER

BY WARREN W. EWING, NORMAN L. KREY, HARTLAND LAW AND ELHEIM LANG

RECEIVED JUNE 17, 1927

PUBLISHED AUGUST 5, 1927

Calcium nitrate crystallizes from water solutions, forming crystals of tetrahydrate, trihydrate, dihydrate or anhydride. If the solution is seeded with a crystal of cadmium nitrate tetrahydrate, a β form of the tetrahydrate may be obtained.

Bassett and Taylor¹ and Taylor and Henderson² have investigated the temperature-composition relations of this system by means of the solubility method. They find that the tetrahydrate melts at 42.7°, the β -tetrahydrate at 39.6° and the trihydrate at 51.1°, and that the dihydrate crystals are in stable equilibrium with the saturated solution only between 48.4° and 51.3°. At this latter temperature a transition takes place, the anhydride and water being formed. They also report a cryohydric temperature at -28.7° and eutectic formation between the tetra-trihydrates and the tri-dihydrates. They remark that the freezing-point method gives anomalous results.

In some work on the vapor pressure of this same system one of the authors³ found, when crystals of the tetrahydrate are dehydrated in a vacuum at 35°, that they did not pass into the lower hydrated or anhydride crystalline forms, but that a solution phase began to appear. This behavior could not be explained by the then existing temperature-composition diagram. The following investigation was undertaken to complete the diagram. We have verified the data of the above investigators, except in the region of the dihydrate curve, and have extended the diagram into the metastable region. The freezing-point method has been used throughout.

Experimental Method

The calcium nitrate used and the method of analysis were the same as described in our vapor-pressure investigation.³ Crystals of tetrahydrate were made by drying the moist crystals over 60 per cent. sulfuric acid in a vacuum desiccator to constant weight. The anhydride was prepared in a similar manner, using phosphorus pentoxide as the drying agent. The various concentrations were made by mixing either water and tetrahydrate, or anhydride and tetrahydrate. By heating the latter mixture

³ Ewing, *THIS JOURNAL*, 49, 1963 (1927).

to 70° and stirring for some time, the anhydride could be brought into solution. All mixtures were analyzed after their freezing points had been determined.

The method of determining the freezing point of the solutions was essentially that of Lidbury,⁴ who has recommended a modification of the usual procedure for viscous solutions, in which equilibrium is attained slowly and in which, therefore, there is a considerable change in concentration before equilibrium is reached. He insulated the freezing tube with thick layers of cotton after crystallization had started, in order to prevent loss of heat to the surroundings.

The authors accomplished this same result by having the bath of the ordinary Beckmann apparatus consist of a vacuum tube with dilute sul-

furic acid for the liquid. Electrodes consisting of loops of copper wire were placed at the top and the bottom. When crystallization started, the bath could be quickly raised, by means of the 110-volt alternating current, to within one degree of the temperature of the melt and could be maintained there. This gave almost adiabatic freezing conditions, and assured a maximum freezing temperature with a minimum change in concentration.

Freezing points and eutectic temperatures were determined by plotting time-temperature cooling curves.

The data obtained are tabulated in Table I.

○ Bassett and Taylor; △ Ewing, Krey, Law and Lang.
Fig. 1.—Freezing point-composition diagram of the system calcium nitrate-water.

Discussion of Results

The results are also expressed graphically in Figs. 1 and 2. For purpose of comparison, the results of Bassett and Taylor are included in these

diagrams. The metastable region is plotted on a large scale in Fig. 2 for the sake of clearness, and to facilitate discussion.

Ice Curve.—For saturated solutions containing up to 44% of calcium nitrate, ice is the solid phase.

Tetrahydrate Curve.—For saturated solutions more concentrated than the cryohydric composition, calcium nitrate tetrahydrate is the solid phase. These equilibria are illustrated by curve A,B,C,D (Fig. 2). For concentrations higher than the tetra-tri eutectic the solid phase is in a metastable condition. Between B and C the solution is supersaturated with respect to the trihydrate, and between C and D with respect to both the tri- and the dihydrates. From vapor-pressure data we have found that this curve extends beyond D, in which region it is supersaturated with respect to the tri- and dihydrates and the anhydride.

Fig. 2.—Detail of the freezing point-composition diagram of the system calcium nitrate-water. O Bassett and Taylor; Δ Ewing, Krey, Law and Lang.

Trihydrate Curve.—B,E,F is the curve for a saturated solution of calcium nitrate in equilibrium with solid calcium nitrate trihydrate. Below B it is supersaturated with respect to the tetrahydrate and between E and F with respect to the dihydrate.

Dihydrate Curve.—C,E,G is the curve for a saturated solution in equilibrium with solid calcium nitrate dihydrate crystals. The reaction $\text{Ca}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O} \rightleftharpoons \text{Ca}(\text{NO}_3)_2 + 2\text{H}_2\text{O}$ represents the transition taking place at G (51.6°). Between E and C the solution is supersaturated with respect to the trihydrate. Vapor-pressure data show that this curve extends below C, in which region the solution is supersaturated with respect to both the tetra- and the trihydrates.

Anhydride Curve.—D,F,G is the saturated solution curve for the anhydride. It extends from below 25° up to its boiling point, 151°, at which temperature its concentration is 79% of calcium nitrate. The anhydride is in a metastable condition below the transition temperature, G.

β $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$.—We have confirmed the existence of the metastable beta modification of the tetrahydrate by seeding a melt of tetrahydrate composition with a crystal of cadmium nitrate tetrahydrate. This gave a freezing point at 39.6°.

Types of Cooling Curves.—For any of the solutions having concentrations between about 70 and 78% several different time-temperature cooling curves are possible. Taking the 76% concentration as an example, four different curves have been obtained. They are as follows:

	F. p.	Solid phase	Eutectic	Solid phases
1)	51.1°	$\text{Ca}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$	50.6°	$\text{Ca}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$ - $\text{Ca}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$
2)	51.1°	$\text{Ca}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$	49.8°	$\text{Ca}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$ - $\text{Ca}(\text{NO}_3)_2$
3)	48°	$\text{Ca}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$	39.6°	$\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ - $\text{Ca}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$
4)	36.8°	$\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$	32.7°	$\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ - $\text{Ca}(\text{NO}_3)_2$

Which of the four possible curves will be obtained depends upon some undetermined factor. Seeding with carefully prepared crystals apparently had little effect, sometimes one modification being obtained, sometimes another. Frequently, while one of the lower crystalline hydrates was crystallizing out in the metastable state, the temperature would suddenly rise, indicating a transformation to the stable modification. This usually occurred when the melt was nearly solid and was probably due to scratching the crystals with the stirrer.

Summary

1. The freezing-point method has been applied to determine the temperature-composition diagram of the binary system calcium nitrate-water.
2. A metastable region has been found and investigated. It lies between the concentrations of about 70 and 78% and between temperatures of 20 and 51°. In this region there are metastable eutectic mixtures containing tetra- and dihydrates, tetrahydrate and anhydride, and trihydrate and anhydride. The saturated solutions in this region are supersaturated with respect to various modifications and their solid constituents are in metastable conditions.

CALCIUM NITRATE. II. THE VAPOR PRESSURE- TEMPERATURE RELATIONS OF THE BINARY SYSTEM CALCIUM NITRATE-WATER

BY WARREN W. EWING

RECEIVED JUNE 17, 1927

PUBLISHED AUGUST 5, 1927

In recent years considerable work has been published on the vapor pressures of hydrated inorganic salts. Three general methods have been used in obtaining the data. Washburn and Heuse¹ have published a critical study of the dynamic method as applied to the vapor pressure lowering of solutions. Baxter and Lansing² have applied this method in a study of the vapor pressures of crystals, obtaining accurate results. The procedure is to pass a known volume of dry air over the mixture of crystals and to analyze for its acquired water content. Carpenter and Jette³ have made, recently, a critical study of the static method and have applied it in determining the vapor pressures of hydrated crystals of various sulfates. In this method the substance is confined over one arm of a manometer and its pressure is compared with that of some known reference material.

Early measurements by these two methods gave conflicting results, but Menzies⁴ has made a critical comparison of the two, using cupric sulfate, and has pointed out that if proper precautions are observed they give concordant results.

Indirect methods have been investigated by Wilson⁵ and by Noyes and Westbrook.⁶ These consist in establishing vapor distribution equilibrium between the hydrates and some reference material; in establishing water distribution equilibrium between the hydrates and some liquid in which the salt is insoluble; and of various other ingenious devices.

The method used in this investigation was the so-called dynamic method developed by Smith and Menzies.⁷ It seems to be rather a static method since the substance is maintained at equilibrium pressure over a confining liquid and the vapor pressure is read from a manometer under static conditions. Derby and Yngve⁸ and Edgar and Swan⁹ have recently used this

method with excellent results. A voluminous bibliography is contained in the references mentioned above.

Although extensive investigation has been carried out in this field, a rather limited amount of reliable data has accumulated, due largely to the fact that most of the recent work has been concerned primarily with a study of methods. In the data available the vapor pressures of most systems are given at only one temperature, usually in the neighborhood of 25°. Vapor pressure-temperature relations have been investigated for only a few systems. These are either of simple type or for systems having such high melting or transition temperatures that only the partial vapor pressure-temperature diagrams have been investigated. The calcium nitrate-water system lends itself admirably to a complete investigation for the following reasons:

The complete temperature-composition diagram¹⁰ has been worked out. The lowest temperature of this system is the cryohydric temperature at -28.7°. The vapor pressure of this point is the same as the known vapor pressure of ice at that temperature. Three hydrates and an anhydride exist. The tetrahydrate melts at 42.7° and the trihydrate at 51.1°. The dihydrate has a transition temperature at 51.6°. There are five eutectics, the lowest being at 32.7°. Complete vapor-pressure data can, therefore, be obtained for all mixtures of crystal systems and for all saturated solutions of the hydrates by making measurements through the temperature range 20 to 60°. Calcium nitrate is very soluble in water, 77.3% at 25° and 79% at its boiling point, 151°. The anhydride is the solid phase at these concentrations. All of the concentrated solutions can be supercooled to very low temperatures. Complete vapor-pressure-temperature data for solutions up to 79% can thus be obtained by measuring the vapor pressures between 20 and 60° and by determining the boiling points of the solutions. The vapor pressure-temperature relations for the three types of systems: mixtures of hydrated crystals, saturated solutions and solutions of various concentrations, give a complete equilibrium diagram for the binary system calcium nitrate-water.

Experimental Methods

Materials.—The calcium nitrate was prepared by treating a high grade of calcium carbonate with nitric acid and was subsequently crystallized out. This material was recrystallized as tetrahydrate, eight times, from water.

Apparatus.—The apparatus used was essentially the isoteniscope of Smith and Menzies,¹¹ with the following modifications. The bulb for the material had a volume of about 25 cc. To insure concentration equilibrium in the solutions an electromagnetic stirrer was enclosed. The bulb also had a side tube for ease in filling and in sealing it on to the isoteniscope. Cottonseed oil was used as the confining liquid. It is superior to a mineral oil in that it wets glass better than water does. The water vapor bubbling

¹⁰ Ewing, Krey, Law and Lang, *THIS JOURNAL*, 49, 1958 (1927).

¹¹ Smith and Menzies, *ibid.*, 32, 1448 (1910).

through the oil had no tendency to condense on the glass in the capillary tube, whereas when a mineral oil was used drops of water frequently formed on the walls of the glass capillary and blocked it up. The large vacuum and air reservoirs were eliminated.

In securing pressure equilibrium small quantities of air were admitted by means of a straight stopcock with a solid core. This core had a small cavity which carried air from the atmosphere side to the vacuum side. The pressure in the system could be lessened in small increments by quickly turning the stopcock between the system and the Cenco Hyvac pump.

Pressure was measured by comparing the mercury level in the manometer tube with that in a barometer tube of the same diameter (1 cm.). Both tubes were connected with the same mercury reservoir at their lower ends. A complete vacuum was assured above the barometer liquid by having it attached to a McLeod gage which registered a pressure of 0.018 mm. of mercury. The difference in heights between the manometer and the barometer mercury was read by means of an accurately graduated brass cathetometer with a vernier reading to 0.05 mm. Readings were corrected to zero degrees. A mercury trap was used instead of a stopcock between the isoteniscope and the remainder of the system. This insured against leakage of air through periods of a month, which was the time required to complete the measurements for some of the systems.

The electrically controlled thermostat could be regulated to $\pm 0.05^\circ$. All temperature measurements were made with mercury in glass thermometers which were compared with a thermometer calibrated by the Bureau of Standards.

Analysis of Samples.—The samples were analyzed by placing them in weighing bottles overnight in an electric oven at 70° , which dried them to about 75% calcium nitrate. They were then cooled, seeded, crystallized and dried over phosphorus pentoxide in a vacuum desiccator, forming the anhydride. Constant weight was usually attained in five days. They were then dried for two weeks longer and check weighings made. All samples were analyzed in duplicate. This method was checked by means of the oxalate method and concordant results were obtained.

Procedure.—The usual procedure was followed in making the readings. Since the two most common criticisms of this method are that adsorbed air is not entirely removed and that equilibrium is difficult to obtain, these two points will be discussed.

When a solid phase is present in work of this type, a large amount of air is adsorbed on the surface. The finer the crystals, the greater is the surface, and consequently a larger amount of air is adsorbed. Most workers have assumed that the evaporation of water of crystallization from hydrated crystals effectually removes this adsorbed gas. Menzies,⁴ however, has demonstrated with cupric sulfate that there is a residual gas which is slowly evolved and that its pressure may amount to as much as 0.3 mm. In this work this adsorbed gas was eliminated by the initial treatment of the sample. The correct amounts of materials were placed in the tensimeter so that, at the lowest temperature measured, the system would be practically all crystalline with not more than one mm. of supernatant saturated solution. This was necessary in order to obtain concentration equilibrium quickly, since it was not possible to stir the contents. The temperature was then raised until but a few small crystals remained. While in this condition the tensimeter was evacuated, intermittently, until a large volume of water vapor had been removed. The

temperature was then lowered and the mass crystallized in contact only with solution and water vapor. This effectually eliminated adsorbed air. As conditions of greater solubility were reached in determining the vapor pressure-temperature curve of the saturated solutions, more water vapor was removed in order to maintain the above-mentioned relations between volumes of solid and saturated solutions. Finally, when proper concentrations existed, eutectic crystallization was induced, still in the presence only of solution and water vapor, and the vapor pressure-temperature curve for these mixtures of crystals was determined. In one case, that of the dihydrate-anhydride, measurements were made on an intimate mixture of dry crystals after they had been thoroughly evacuated to remove adsorbed air and the results checked those obtained by the above-mentioned preparation.

Pressure equilibrium between mixtures of hydrated crystals and water vapor is attained quickly or slowly according to some specific nature of the substance. By grinding the crystals together to form an intimate mixture equilibrium is hastened. Some hydrated crystals can be kept an indefinite length of time under conditions at which they would be expected to dehydrate. In this metastable condition a scratch will start dehydration. In our vapor-pressure measurements on the mixtures of crystals of the tetra- and dihydrates and of the tetrahydrate and the anhydride, the tetrahydrate was apparently in such a metastable condition. The above-described method of forming a mixture of the crystals by eutectic formation gives a very intimate mixture of the crystals. Pressure equilibrium was established within four hours. However, the final measurement was made only after 24 hours. The saturated solution required about the same time interval. Solutions, when only one phase was present, came to equilibrium in a half hour, but two hours were allowed before making the final measurement. Two points on each solution curve represent overnight time intervals.

Accuracy of Results.—The difference in heights of the mercury columns could be read to within 0.05 mm. of mercury. A variation of 0.05° in temperature at 60° gives, for the most dilute solution, a change in pressure of 0.3 mm., and for the most concentrated solution, a pressure change of 0.05 mm. At 20° these changes are respectively, 0.07 mm. and 0.01 mm. For mixtures of crystals and for saturated solutions the maximum variation, per change of 0.05° , is 0.05 mm. at the higher temperatures, and 0.01 mm. at 20° . Therefore, the change in pressure, due to variation in the temperature of the thermostat, is negligible except in the case of the dilute solutions at the higher temperatures. At these higher temperatures the most probable vapor pressures were determined by following the change in vapor pressure with the change in temperature as the heaters of the thermostat went on and off. The error here

is probably as great as 0.1 mm. The accuracy of the results is further attested by the fact that with but a half-dozen exceptions all points fall within 0.1 mm. of the plotted curves.

A preliminary test of the apparatus was made using cupric sulfate. The vapor pressure of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ - $\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$ was found to be 7.8 mm. Menzies⁴ finds 7.80 mm. by the dynamic method and 7.74 mm. by the static method, while Wilson⁵ obtains 7.80 by an indirect method. Other investigators find values scattered from 7.0 to 8.5 mm.

A final check was made by determining the vapor pressure of water at 20, 30, 40, 50 and 60°. The results are within 0.1 mm. of those of Scheel and Heuse.

From the above considerations the author estimates a maximum error of 0.1 mm. in the results presented.

Boiling Points of Solutions.—The boiling points of the solutions were determined by the bulblet method of Smith and Menzies.¹² The bulb had a volume of 10 cc. and 3 to 5g. samples were taken. These samples were analyzed in the usual manner after the runs. Paraffin wax having a melting point of about 55° was used as the confining liquid. This was a convenient liquid because in removing the bulb from the bath some of the bath liquid always sucked back into it. This solidified and so permitted the removal of the uncontaminated solution for analysis. The temperature was maintained constant to within 0.1° by means of an electric coil and vigorous stirring.

The following boiling points for the various concentrations were obtained: 21.5% $\text{Ca}(\text{NO}_3)_2$, 102.1°C.; 32.1%, 104.1°; 51.1%, 111.8°; 60.5%, 119.6°; 69.9%, 132.0°; 75.0%, 142.8°; 77.4%, 147.3°. By plotting these data, boiling points for any concentration may be obtained. This gives the following boiling points for the concentrations for which solution vapor pressures were measured: 20.2%, 102°; 30.6%, 104°; 49.6%, 111°; 59.1%, 118.3°; 66.6%, 126.7°; 72.2%, 136.0°; 74.2%, 140.5°; 74.7%, 141.5°; 76.3%, 145.0°; 76.9%, 146.4°; 77.4%, 147.5°. At these temperatures the vapor pressures of these various solutions are 760 mm.

Gerlach¹³ gives results uniformly lower than these for concentrations above 50%. His results are evidently in error since he obtains the boiling point of 152° for a saturated solution containing 82% of calcium nitrate.

Discussion of Results

The vapor-pressure data obtained are tabulated in Tables I, II and III. For clearness of presentation and to facilitate discussion, the data are also plotted in the various curves. The reader should also refer to the temperature-composition diagram in the preceding article.

* % = g. $\text{Ca}(\text{NO}_3)_2$ per 100 g. of solution.

Saturated Solution Curves.—In Fig. 1, A,A,A is the vapor pressure-temperature curve for a saturated solution in contact with crystals of the tetrahydrate; B,B,B the trihydrate; C,C,C the dihydrate; and D,D,D the anhydride. In each of these saturated solutions the same supersaturated conditions for the solutions and the same metastable conditions for the crystals prevail as described in the composition-temperature discussion in the preceding article.

On the curve for the saturated solution in contact with crystals of the tetrahydrate the vapor pressure rises rapidly with the temperature up to about 37°. At this temperature the rate of increase slows down, with rise in temperature, due to the increased solubility becoming the predominating factor. At 41° the vapor pressure even begins to decrease with rise in temperature until the melting point, 42.7°, of the tetrahydrate is reached. The reflex portion of the curve represents the saturated solution in unstable equilibrium with respect to the other crystalline forms. The initial region of this curve may be extrapolated to meet the vapor pressure of ice, 0.321 mm., at the cryohydric temperature, - 28.7°. This is permissible because at this condition ice, tetrahydrate, saturated solution and water vapor are in equilibrium and, therefore, the vapor pressure of the system is the same as the vapor pressure of any of the constituents. The curve for the trihydrate is similar to that for the tetrahydrate. The

dihydrate and the anhydride curves do not show a region of decrease in vapor pressure with increase in temperature. This is because the dihydrate reaches its transition temperature before its melting point is reached, and the saturated solution boils (151°) below the melting point of the anhydride. The vapor pressure of water above this solution should approach zero as the composition of the saturated solution approaches pure anhydride and the temperature approaches the melting point of the anhydride.

Fig. 1.—Vapor pressure-temperature relations for saturated solutions and for mixtures of hydrates of calcium nitrate.

Mixtures of Crystals.—At the temperatures at which the saturated solution curves meet, the pressure is the vapor pressure of the eutectic equilibrium for the four phases crystal + crystal + saturated solution + water vapor, except in the case of the dihydrate and the anhydride saturated solutions, where it is the vapor pressure of the transition equilibrium $\text{Ca}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O} \rightleftharpoons \text{Ca}(\text{NO}_3)_2 + 2\text{H}_2\text{O}$. Here, too, the same four phases are present. At lower temperatures the saturated solution phase disappears and the vapor pressure is that of the mixture of two crystalline forms.

These conditions are represented by curve E, Fig. 1, for a mixture of tetra- and trihydrates; F for tetra-di-; G for tetra-anhydride; H for tri-di-;

Fig. 2—Mixture of crystals.

and K for di-anhydride. The curve for the trihydrate-anhydride mixture was not determined. It would lie about 0.2 mm. above that for the di-

Fig. 3.—Vapor pressures of solutions of calcium nitrate in water.

hydrate-anhydride. This is but slightly greater than the experimental error of measurement.

In Fig. 2, the vapor pressure of these mixtures is plotted against the inverse of the absolute temperature, on a logarithmic scale for the pressure, the letters E, F, G, H and K having the same significance as above. Except for one point on the tetra-anhydride curve, all experimental values fall upon the straight lines. This is in agreement with the results of other investigators on this type of system.

Solution Curves.—Fig. 3 gives the vapor pressure-temperature relations of solutions of calcium nitrate in water for various concentrations from 20 to 77%. A solution of calcium nitrate saturated with the anhydride at 25° contains 77.3% of calcium nitrate. The vapor pressure data for water and ice are those of Scheel and Heuse.¹⁴

Fig. 4.—Vapor pressure-composition isotherms for calcium nitrate solutions.

The 20.2% and the 30.6% curves have been extrapolated to meet the ice curve at the temperatures at which they are in equilibrium with ice. If these data are plotted with the logarithm of the pressure against the inverse of the temperature as coördinates, apparently straight lines are obtained for temperatures up to 60°. The same holds for water. These lines are not parallel but converge in the direction of the higher temperatures. Above 60°, however, the value of $\ln P$ for water falls below

¹⁴ Scheel and Heuse, *Ann. Physik* [4] 29, 723 (1909); [4] 31, 715 (1910).

the straight line, the divergence increasing steadily up to its critical temperature. If values of the vapor pressure (760 mm.) at the boiling temperatures of these various solutions are plotted on this same diagram, these curves also show a change in slope similar to that of water.

Temperature-Composition Diagrams from Vapor-Pressure Data.—Fig. 4 contains vapor pressure-composition isotherms plotted from the solution data in Table III. From these curves it is possible to plot any number of additional vapor pressure-temperature curves for solutions. If a sufficient number of such curves are superimposed upon the saturated solution curves in Fig. 1, it is possible to obtain data for a complete temperature-composition diagram, at the vapor pressures of the systems, for this system. The point at which any given solution curve crosses any given saturated solution curve gives the composition and temperature data for that solution. Data obtained in this manner give a temperature-composition diagram which is, within experimental error, the same as Fig. 2 in the preceding article, with the additions that the unstable saturated solution curves extend beyond the various eutectics.

Thermal data for these systems are being measured in this Laboratory. Thermal data calculated from these vapor-pressure measurements will be presented when this work is completed.

Summary

Complete vapor-pressure-temperature relations of the binary system calcium nitrate-water have been determined. This involved measurements at various temperatures from 20° to the boiling points of the solutions, and for various concentrations from 20% to the saturated solution of the anhydride. The systems in this region contain dilute solutions and supersaturated solutions, stable and unstable saturated solutions, and stable and metastable mixtures of crystals.

In the mixtures of crystals, $\ln P$ is proportional to $1/T$. Solutions apparently obey the same law up to temperatures of about 60°.

Temperature-composition diagrams can be constructed from vapor pressure-temperature data.

THE VAPOR PRESSURE OF THE SATURATED AQUEOUS SOLUTIONS OF CERTAIN SALTSBY H. GENEVA LEOPOLD¹ AND JOHN JOHNSTON

RECEIVED JUNE 21, 1927

PUBLISHED AUGUST 5, 1927

In the course of an investigation of the absorption of water by various materials, it was necessary to maintain atmospheres of constant humidity, which is best achieved by the use of a saturated salt solution. A survey of the literature on the vapor pressure of saturated salt solutions showed the data to be incomplete and of insufficient accuracy for our purpose; for much of the work consists of single measurements at a single temperature, and in many cases the several results differ by far more than the supposed experimental error. We undertook, therefore, a redetermination of the vapor pressure of some saturated solutions over the temperature range 20 to 50°, and believe that the uncertainty in the final results is not greater than 0.05 mm.; the salts used were sodium chloride, potassium chloride, sodium sulfate, potassium sulfate, potassium bichromate and, in addition, sodium chloride and potassium chloride together. Such data, apart from their practical utility, yield also a measure of the activity of both the salt and the water in these solutions, and this constitutes the best means of evaluating these quantities at temperatures other than in the freezing range of the solutions.

We have correlated our results with the data available on the vapor pressure of unsaturated solutions of the same salts by means of a sensitive method of plotting. This led us to observe that the vapor pressure of a saturated solution—presumably, therefore, also of some unsaturated solutions—attains to its final value only after the solution has been maintained at constant temperature for a period of 24 hours. This observation probably accounts for the lesser accuracy of many prior results, for it has been usual to record the pressure observed at the end of a period, at a given temperature, measured in minutes rather than in hours.

Experimental

The vapor pressure was measured directly, the form of apparatus used being that described by Johnston.² The essential feature is that between the bulb containing the solution and the main manometer, there is in a sort of double U-tube, a small mercury trap, the levels of which are adjusted by appropriate manipulation of stopcocks controlling the admission or extraction of air; after the whole apparatus has been thoroughly evacuated, this mercury is made the confining liquid and subsidiary manometer, and at pressures less than 60 mm. is the only manometer needed. The only modifications were the interposition of a bulb containing phosphorus pentoxide, to prevent access of

¹ From the dissertation presented to the Graduate School of Yale University, in June, 1926, by H. Geneva Leopold in candidacy for the degree of Doctor of Philosophy.

² Johnston, *Z. physik. Chem.*, **62**, 347 (1908).

water to the main manometer and the pump, and of a trap to prevent spattering of the solution over into the subsidiary manometer. The difference in level of the mercury columns was read by means of a depth gage,³ the vertical rod of which was set in bearings in a rigid brass frame; on its cross bar was mounted a small reading lens, at the center of which was glued a pointed piece of paper. When this is set up in front of, with a mirror at an equal distance behind, the manometer, the image of the paper point is in the plane of the manometer, and so errors due to parallax are avoided. With this simple form of cathetometer, the uncertainty in the readings is about 0.03 or 0.04 mm. The observed pressures were all reduced to their equivalent in terms of mercury at 0°.

The salt solution, previously heated to boiling, was introduced into the bulb, which was then sealed off; such air as had been retained by the solution was removed by continued pumping of vapor from the warm solution, this process being repeated until the observed final vapor pressure remained unchanged upon further pumping. The removal of the dissolved air is more difficult than we had anticipated; a period of 3 or 4 days is in many cases needed.⁴ Even so, when the temperature of the solution has been changed, the pressure does not attain to a new constant value until the lapse of several hours; consequently we use a thermometer and took readings, with frequent shaking of the solution bulbs, over a period of at least 24 hours. This gradual change to the equilibrium pressure, which may differ from the initial pressure by 0.2–0.3 mm., occurs after each evacuation of vapor from the solution, and is therefore due presumably to the slow equalization of some degree of undersaturation or supersaturation of the salt at the surface of the solution.

Each datum in Table I is the mean of 6 or more readings taken over an interval of at least 24 hours, and in many cases longer, during which the temperature was kept constant to $\pm 0.01^\circ$. The large number of observations made before we realized that a period of an hour at a given temperature is insufficient, have been omitted entirely; when plotted in the terms used in this paper, these points lie (along with those of previous workers) in a cluster so large that one could not determine in which direction to produce the curve.

Table I, Col. 2 contains the molality (M) of the saturated solution at t , as derived from the "best" curve drawn through a large-scale plot of the solubility data available.⁵ Cols. 3 and 4 list the vapor pressure at t° of water⁶ (p_0) and of the solution

⁵ Some points on the curve chosen may be found in Table IV. The individual references are: Potassium chloride: Berkeley, *Trans. Roy. Soc. (London)*, 203A, 189 (1904); Brönsted, *Z. physik. Chem.*, 80, 208 (1912); 82, 621 (1913); Andreae, *J. prakt. Chem.*, [2] 29, 456 (1884); de Coppet, *Ann. chim. phys.*, [5] 30, 426 (1883); Tilden and Shenstone, *Proc. Roy. Soc. (London)*, 35, 345 (1883); Meusser, *Z. anorg. Chem.*, 44, 79 (1905); Foote, *Amer. Chem. J.*, 35, 238 (1906); Sudhaus and Miner, *Jahrg. Beil. Bd.*, 37, 18 (1914); Amadori and Pampanini, *Atti. accad. Lincei*, 20, II, 475 (1911). Sodium chloride: Berkeley, *Trans. Roy. Soc. (London)*, 203A, 189 (1904); Andreae, *J. prakt. Chem.*, [2] 29, 456 (1884); Raupenstrauch, *Monatsh.*, 6, 563 (1885); Taylor, *J. Phys. Chem.*, 1, 718 (1897); Moller, *Pogg. Ann.*, 117, 386 (1862); de Coppet, *Ann. chim. phys.*,

(p), expressed in millimeters of mercury at 0° ; and the last column lists the molal relative vapor pressure lowering, calculated from these data, a quantity which is plotted against the molality in the figures.

A Graphical Method of Evaluating Vapor-Pressure Data on Solutions.—The accuracy of vapor-pressure data has commonly been estimated from their regularity; but this criterion fails in the presence of a constant, or regular, error such as the presence of air or the use of an inaccurate thermometer. A much better criterion is the ratio of the vapor pressure of the solution to that of water (solvent) at the same temperature; in other words, to compare the relative humidity (p/p_0) which is affected differently at different temperatures by a constant error in p . The use of this ratio also shows up chance errors in p —since p/p_0 must vary regularly with temperature—provided that the vapor-pressure curve of the solvent has been accurately determined. A still more sensitive criterion, since for most salt solutions p/p_0 is not far from unity, is $1 - p/p_0$ or $(p_0 - p)/p_0$, the relative lowering of vapor pressure; and if this quantity is divided by the molality (M), the relative molal lowering of vapor pressure (Δ) so derived is found to change quite slowly with change in the salt concentration. Therefore a plot, even on quite a small scale, of this function (Δ) against the molality shows up the degree of accuracy of the experimental results; indeed, with all except the very best data, the points are so scattered that one finds difficulty in deciding just how the curve should be drawn.

As an instance of the fact that Δ changes slowly with concentration, the values of Δ derived from the measurements of Lovelace, Frazer and Sease⁴ in solutions of potassium chloride above 1 M are as follows:

M	1.2461	1.5099	1.7072	1.9938	2.2450	2.4916	3.0017	3.5783	4.0070
$\Delta \times 10^4$	3159	3166	3167	3169	3173	3180	3200	3220	3233

This regularity, which shows that these results are accurate to 0.001 mm., as claimed by the authors, contrasts with the irregular values of Δ lying between 0.30 and 0.33 as derived from the work of other authors in this same range of concentration.

Let us now consider the effect of change of temperature upon the function [5] 30, 426 (1883); Gay-Lussac, *Ann. chim. phys.*, [2] 11, 310 (1819). Sodium sulfate: Richards and Yngve, *THIS JOURNAL*, 40, 164 (1918); Takenchi, *Mem. Coll. Kyoto*, 1, 249 (1915); Wuite, *Z. physik. Chem.*, 86, 349 (1914); Berkeley, *Trans. Roy. Soc. (London)*, 203A, 189 (1904); Tilden and Shenstone, *Proc. Roy. Soc. (London)*, 35, 345 (1883); Loewel, *Ann. chim. phys.*, [3] 49, 50 (1857); Gay-Lussac, *Ann. chim. phys.*, 11, 312 (1819). tion Δ . If we calculate, from measurements at a series of temperatures of the vapor pressure of a solution of constant composition, the values of Δ —or what suffices in this case, the relative humidity p/p_0 —we find that the values at adjacent temperatures differ by as much as those at the highest and lowest temperature. In other words, *within the accuracy of the data available*, the relative humidity—and hence Δ —may be regarded as independent of temperature. This is the principle, first stated by Princeps, commonly known as Babo's law;^{7a} and is equivalent to the statement that the activity of water in a solution of constant concentration is substantially independent of the temperature. It is quite clear, however, that if there were measurements of sufficient accuracy, on a solution of constant molality at a series of temperatures, we would observe a slight increase in relative humidity with increase of temperature.^{7b} This rate of increase would be parallel to the rate at which the average degree of "hydration" of the ions of the salt decreases with rising temperature, and it would seem that this trend should be most marked for those salts which ordinarily form the largest hydrates, a view which is substantiated by the results for sodium sulfate.

The fact that, for a solution of constant molality, the relative humidity, and hence the function Δ , is independent of temperature *within the limits of accuracy of existing data*, enables us to omit temperature from further consideration, and so to bring together on a single plane diagram all of the data upon solutions of a salt from freezing range to the boiling point of a saturated solution. On this diagram the coördinates are molality and Δ , the relative lowering of vapor pressure of water per mole of solute. In the few cases in which the vapor pressure of a single solution was measured at a series of temperatures, we used the average value of Δ ; in general, for a given value of M , there is available only a single value of Δ , but these may refer to quite different temperatures. This plot thus allows one to correlate results from various sources, to estimate their relative accuracy and to derive throughout the range of concentration definitive values of higher accuracy than have hitherto been available. It is much more sensitive than the method proposed by Bencowitz,⁸ namely, to plot $\log p/p_0$ against $1/T$; for on this basis he is able to represent by straight lines data which our figures indicate are of doubtful accuracy.

^{7a} Recent data which confirm this principle, *within the accuracy of the measurements*, are those on cane sugar solutions by Perman and Saunders (*Trans. Faraday Soc.*, **19**, 112 (1923)). This is further exemplified by a comparison of the work of Sidgwick and Ewbank (*J. Chem. Soc.*, **125**, 2268 (1924)) on solutions of potassium chloride, sodium chloride and potassium sulfate at 5°, with that of Tammann (*Ann. Physik*, **24**, 523, (1885)) on the solutions of these salts at 100°.

^{7b} See, for example, in the very recent results of Perman and Lovett (*Trans. Faraday Soc.*, **22**, 1 (1926)) on urea solutions over the range 40–80°.

⁸ Bencowitz, *J. Phys. Chem.*, **29**, 1432 (1925).

Solutions of Potassium Chloride (Fig. 1).—The data made use of in the preparation of this figure are listed in the following tabular statement with respect to author (with the abbreviated designating letter), temperature range (s denoting the saturated solution), general method of measurement, and reference.

It will be noticed that we have included three sets of measurements of depression of freezing point (δ), this having been done mainly to enable us to continue the curve to zero concentration. These data, for the more dilute solutions, were transformed to our variable by means of the equation²¹ $\log p/p_0 = \log a = -0.004211\delta - 0.00000228\delta^2$, in which a , the relative activity of the water in the solution, is the same as p/p_0 . The foregoing equation is applicable only to solutions so dilute

that the heat of dilution is negligible; otherwise, one must take this factor into account and correct the foregoing results by means of the equation^{21a}

$$\log \frac{a'}{a''} = -\bar{L} \frac{T'' - T'}{2.303RT'T''} + (\bar{C} - \bar{C}_0) \left[\frac{T''(T'' - T')}{2.303RT'T''} - \frac{1}{R} \log \frac{T''}{T'} \right]$$

in which T'' is the temperature chosen for the calculations (in our case 298.1°) and T' is 273.1 - δ ; \bar{L} is the molal heat of dilution at T'' , and \bar{C} and \bar{C}_0 , respectively, the partial molal heat capacity of the solvent in the solution and of the pure solvent; a' is calculated from the simple equation above, and the corrected value a'' is set equal to p/p_0 .

In the application of this equation to the data of Rodebush, the value of \bar{L} was taken from the work of Wüst and Lange,²² and \bar{C} was evaluated from the results of Randall and Bisson²³ by plotting the specific heat of the solution against the concentration in terms of moles of water per mole of salt, and taking the slope of this curve at the several molalities. These values, together with the uncorrected (from a') and corrected values of Δ , are given in Table II.

TABLE II

THE RELATIVE MOLAL VAPOR-PRESSURE LOWERING (Δ) OF SOLUTIONS OF POTASSIUM CHLORIDE, DERIVED FROM THE FREEZING-POINT DATA OF RODEBUSH, CORRECTED FOR THE HEAT OF DILUTION

Moles KCl per 1000 g. H ₂ O M	(Cal. per mole H ₂ O) \bar{L}	\bar{C}	$\frac{p_0 - p}{p_0 M}$	Corr. $\Delta = \frac{p_0 - p}{p_0 M}$
0.0	0.0	17.98
.951	- 2.32	17.96	0.03089	0.03136
1.445	- 5.53	17.93	.03064	.03142
2.331	-13.20	17.86	.03024	.03149
3.043	-19.35	17.77	.03005	.03159
3.192	-20.54	17.75	.03004	.03162
3.300	-21.55	17.74	.02992	.03154

It may be mentioned that we also attempted to derive Δ from the freezing-point data by means of the consideration that the vapor pressure of the solution is the same as that of the ice with which it is in equilibrium. But the values calculated from this basis and the most recent vapor-pressure table²⁴ for ice and water below 0° were not compatible with other data and, indeed, were inconsistent among themselves.

Fig. 1 shows the molal relative vapor-pressure lowering (Δ) caused by potassium chloride in solution as a single curve over the range from extremely dilute to boiling saturated solutions. From 0.3 to 0.8 molal the

curve has been dotted as there is some uncertainty on account of the hump in the curve expressing the results of Lovelace, Frazer and Sease alone, which over the rest of the range are clearly the best available; this hump may well be real, for they claim that the irregularity is greater than the possible experimental error, 0.001 in Δ corresponding to 0.0175 in the measured depression. The points listed in Table II lie below the curve, but the difference corresponds to less than 0.05 mm. in p ; this slight discrepancy is probably due to the fact that the heat values used refer to 25° (there being no others available), whereas one should use thermal data which refer to the same temperature as the results to be transformed and corrected.

Fig. 1 —The relative molal vapor-pressure lowering of solutions of potassium chloride.

Altogether we venture to believe that this curve gives the best representation of the vapor-pressure data of solutions of potassium chloride now available, it tends to exaggerate the discrepancies, many of the points being off by no more than 0.1 mm. It may be pointed out that the points derived from the measured boiling temperature of the saturated solution all lie considerably below the natural prolongation of the curve—and the same is true for each one of the salts investigated; this corresponds to a somewhat too high vapor pressure or too low surface concentration, and is in line with our repeated observation that the vapor pressure of a saturated solution only attains to its definitive equilibrium value after an interval measured in hours.

Solutions of Sodium Chloride (Fig. 2). The data made use of are listed below, as in the previous case.

Author	Symbol	Δ temperature range, °C.	Molality range	Method
Berkeley ^{10a}	B	107.5	6.760(s)	Boiling temp.
Berkeley and Appleby ^{10b}	BA	108	6.766(s)	Boiling temp.
Bousfield and Bousfield ²⁵	B ²	18	0.56-6.113(s)	Isopiestic solns.

This paper.....	L	20-50	6.130(s)-6.277(s)	Static

In this case again two sets of freezing data were employed and converted as before into the variable Δ by means of the heat data as determined by Randall and Bisson, and computed by Lewis and Randall.³¹ The uncorrected and corrected values of Δ for the several molalities investigated by Rodebush are:

M	1.045	1.526	2.429	3.057	3.806	4.739	5.201
$\Delta \times 10^6$ (uncorr.)	3181	3212	3279	3339	3432	3535	3596
$\Delta \times 10^5$	3254	3317	3434	3520	3645	3769	3835

These points again lie slightly below our best curve, and probably for the same reason as in the case of potassium chloride.

The experimental work of Bousfield and Bousfield consisted essentially in a comparison of the concentrations of isopiestic solutions of the chlorides of potassium, sodium and lithium. The numerical results, as given by them, are based upon a vapor-pressure curve for sodium chloride solutions (particularly at the lower concentrations) as standard, but this curve is not in satisfactory agreement with the best of the other data cited in Fig. 2 nor do their values for potassium chloride fit the curve in Fig. 1. On the contrary, if their results are recomputed on the basis of the curve (Fig. 1) as standard, the results for sodium chloride lie very close to the curve in Fig. 2, the difference corresponding to only 0.0015 mm. at the

³¹ Ref. 21, p. 350.

lowest concentration and to 0.011 mm. at the highest. Accordingly, this basis was used to evaluate their results for both sodium chloride and for lithium chloride, which also now show excellent agreement with the best curve based on the other data available.

Solutions Saturated with Both Potassium and Sodium Chloride.—In this the method of plotting could not be used, because the molality of these saturated solutions has not been accurately determined.

Solutions of Lithium Chloride (Fig. 3).—Although we did no experimental work on solutions of lithium chloride, it seemed worth while to exhibit its curve for comparison with the other halides. The only data available are those of Lovelace, Bahlke and Frazer³² (F) at 20° for the range 0.097–1.032 *M*, using a differential method; the isopiestic results of

Fig. 2.—The relative molal vapor-pressure lowering of solutions of sodium chloride.

Bousfield and Bousfield (B²) already alluded to; and the freezing-point depression at 0.01 and 0.02 *M* as given by Noyes and Falk³³ (NF). The first-named results are again obviously of a high order of accuracy, and the others are in excellent accord with them.

Comparison of the Curves for the Alkali Halides.—The three curves all start from the same point, Δ for zero concentration of a uni-univalent salt being 0.0355; all three drop sharply to a minimum and then rise again, the most rapid rise corresponding to the minimum at the lowest concentration, and conversely. It is significant that, at concentrations beyond that at which the minimum occurs, the slope is greatest for lithium chloride,

³² Lovelace, Bahlke and Frazer, *THIS JOURNAL*, 45, 2930 (1923).

³³ Noyes and Falk, *ibid.*, 32, 1011 (1910).

which forms a monohydrate stable between 13 and 98°; less for sodium chloride, which appears as hydrate only below 0°; and least for potassium chloride with no known solid hydrates. If hydrates form in solution, the net concentration of the water will be less than its gross concentration, and the observed vapor pressure less than it would otherwise be; this divergence increases with concentration as the relative amount of water

Fig. 3.—The relative molal vapor-pressure lowering of solutions of the chlorides of potassium, sodium and lithium.

decreases. On this basis Δ would, with increasing concentration, increase most rapidly in the case of the salt which we would expect to be hydrated in solution to the greatest extent; this is in harmony with the results for the three halides, and also for the two alkali sulfates.

Sodium Sulfate Solutions (Fig. 4).—The most complete work is that of Wuite³⁴ (W) who made static measurements on solutions saturated

³⁴ Wuite, *Z. physik. Chem.*, **86**, 349 (1914).

with the anhydrous salt at $19.4\text{--}50.4^\circ$ ($3.728\text{--}3.283\text{ }M$) and with the decahydrate at $21.6\text{--}32.4^\circ$ ($1.447\text{--}3.510\text{ }M$), and supplemented these by solubility determinations. There are also data by Tammann^{7a} over the unsaturated range $0.94\text{--}3.44\text{ }M$, and freezing-point data on dilute solutions ($0.025\text{--}0.25\text{ }M$) are given by Noyes and Falk³³ (NF). Some other considerations³⁵ led us to believe that Wuite's value at the transition point is rather low, as indeed we found it to be by 0.9 mm. ; and the measurements at other temperatures indicate that most of Wuite's values are low—this being another illustration of the necessity of maintaining the solution for a period of hours at the temperature before the definitive observation is made. We believe that our points are the more accurate, but have drawn a dotted curve through Wuite's. A few of Tammann's points have been inserted, as well as the values calculated from the freezing data, but no attempt was made to draw a single continuous curve for the decahydrate.

In this case it is obvious that the relative vapor pressure of a solution of constant composition cannot be independent of temperature, for there are two branches of the curve with divergent values of Δ (at different temperatures) for the same molality of solution.

Solutions of Potassium Sulfate and of Potassium Dichromate (Fig. 5).—For potassium sulfate there are data by Berkeley^{10a} and Berkeley and Appleby^{10b} on the boiling temperature (101° , 101.39°) of the saturated solution (1.396 , $1.399\text{ }M$); a similar observation by Brönsted¹¹ (100° , $1.388\text{ }M$); freezing data by Hovorka and Rodebush¹⁵ ($0.001\text{--}0.001\text{ }M$) and from Noyes and Falk³³ ($0.045\text{--}0.25\text{ }M$); together with our own direct measurements.

The curve is similar to that for lithium chloride, though Δ is of course

³⁵ See Norton and Johnston, *Am. J. Sci.*, 12, 467 (1926).

Fig. 4.—The relative molal vapor-pressure lowering of solutions of sodium sulfate.

higher, being above 0.055 at zero concentration. It will be observed that the boiling data again lie considerably below the probable course of the curve.

For potassium dichromate there are no data except ours; in this case the curve appears to have a negative slope over the range investigated. This implies that the complete curve from zero concentration would first fall, then rise and then fall again; but the data are insufficient to decide this question; this course, it may be remarked, would in effect be similar to that of the curve for potassium chloride if the "hump" is real.

Fig 5.—The relative molal vapor-pressure lowering of solutions of potassium sulfate (left) and potassium dichromate (right).

Conclusion

From the curves for the several salts, plotted on a large scale, values at a series of concentrations were read off; they are presented in Table III. Similarly we have derived, and give in Table IV, values of the percentage humidity in equilibrium with saturated solutions of the several salts at a series of temperatures, and believe that these are more reliable than those hitherto available for these salts. We have also made use of the data to plot the molality of the solutions against that of the isopiestic solution of potassium chloride; from the curves, which are of gentle curvature (though they cannot be represented over the whole range by a single quadratic equation) we have read off the results listed in Table V for four of the salts,

Summary

The vapor pressure of the solution saturated with potassium chloride, sodium chloride, potassium sulfate, sodium sulfate, potassium dichromate, and with both potassium chloride and sodium chloride has been measured by a static method, with an accuracy of about 0.05 mm., over the temperature range 20 to 50°. Each solution was kept at constant temperature for at least 24 hours before the definitive reading was made; inattention to this necessary precaution by most previous authors has resulted in values which are slightly in error, as if the concentration of the solution at its surface was not precisely the saturation concentration. The various data for solutions of each salt up to saturation have been correlated by a sensitive method of plotting; the resulting curves are a more reliable picture of the vapor pressure of these solutions than has hitherto been available.

THE FREE ENERGY OF AURIC OXIDE AS DETERMINED FROM MEASUREMENTS OF THE GOLD-AURIC OXIDE ELECTRODE¹

BY T. F. BUEHRER AND W. E. ROSEVEARE

RECEIVED JULY 1, 1927

PUBLISHED AUGUST 5, 1927

The purpose of this investigation was to measure the potential of the gold-auric oxide electrode and to calculate the free energy of formation of auric oxide from its elements at 298° A.

The cell chosen for these measurements was H_2 (g), H_2SO_4 (x-M), Au_2O_3 (s), Au (s). A careful search of the literature showed that very little work had been done on the potential of the gold-auric oxide electrode. Jirsa and Jelinek² in their work on the anodic oxidation of gold arrived at a value of 1.36 volts, referred to hydrogen. The aim of the present research was to extend the accuracy of this value, if possible, by the use of cell substances of such purity and homogeneity that true equilibrium would readily be established within the cells.

Materials and Apparatus

The measurements were made with auric oxide obtained by precipitation from chloro-auric acid by means of potassium hydroxide, followed by a purification process as described in a previous paper by the authors.³ The gold was obtained in excellent crystalline form by reduction of chloro-auric acid with ferrous sulfate. The cells were of the type devised by Lewis and Rupert,⁴ modified to contain two hydrogen electrodes and three gold half-cells, to make possible a triplicate series of measurements under identical conditions. Three concentrations of sulfuric acid were employed: 1.024 *M*, 0.100 *M* and 0.0100 *M*. The auric oxide as well as the gold crystals were equilibrated with the sulfuric acid solutions for 12 hours before being introduced into the cells. Hydrogen from the electrolysis of potassium hydroxide was used in the cells. All electromotive-force measurements were made with a Type K Leeds and Northrup potentiometer. The water-bath containing the cells was maintained at $25^\circ \pm 0.1^\circ$. The cells came to equilibrium promptly in most cases, the more so when the more concentrated solutions of sulfuric acid were used. The measurements are summarized in Table I.

The electromotive force is seen to be substantially independent of the concentration of the sulfuric acid, as is to be expected from the cell reaction.

TABLE I

DIRECT MEASUREMENTS OF POTENTIAL OF THE GOLD-AURIC OXIDE ELECTRODE AGAINST THE HYDROGEN ELECTRODE AT 25°

Concn H ₂ SO ₄	Cell 1	Cell 2	E.m.f. (volts)	Cell 3	Mean
1.024	1.363 ₄	1.363 ₄		...	1.363 ₄
0.1000	1.362 ₇	1.363 ₀		1.364 ₉	1.363 ₈
.0100	1.363 ₈	1.364 ₂		1.363 ₇	1.363 ₉

General average = 1.364 ± 0.001 volts

These results have recently been confirmed independently by Gerke and Rourke, in an investigation⁵ in which they measured the potential of the cell Hg(l), Hg₂SO₄(s), H₂SO₄(x-M), Au₂O₃(s), Au(s) and from the known value of the potential cell H₂(g), H₂SO₄(x-M), Hg₂SO₄(s), Hg(l) calculated the electromotive force of the gold-auric oxide electrode against the hydrogen electrode. Their calculated mean value was 1.362 ± 0.002 volts.

The Free Energy of Auric Oxide

To obtain the free energy of auric oxide from these measurements, it is necessary to combine the free energy of the reaction tending to take place in the above cell with the free energy of formation of 1 mole of liquid water from its elements at 298° Å., which was calculated by Lewis and Randall⁶ to be -56,560 calories. We shall use the value of the e.m.f. of the gold-auric oxide electrode Au, Au₂O₃, H⁺, E° = -1.363 ± 0.001 volts, which is the average of our result, and that of Gerke and Rourke.

Subtracting the first from the second of these equations, we obtain:

This high positive free energy of formation of auric oxide indicates that it must be very unstable and, therefore, have a high dissociation pressure. The auric oxide involved in the above equation is very probably not Au₂O₃, but a hydrated form of the oxide. Because of its instability, it is a question whether the true degree of hydration of auric oxide can be experimentally determined.

The Dissociation Pressure of Auric Oxide

The dissociation pressure of auric oxide as calculated by the thermodynamic equation $\Delta F = -RT \ln K$ is found at 298° Å. to be 2.13×10^9 atmospheres.

It was also considered of interest to calculate the entropy change attending the formation of 1 mole of auric oxide from its elements at 298° Å.

⁵ Gerke and Rourke, THIS JOURNAL, 49, 1855 (1927).

⁶ Lewis and Randall, "Thermodynamics and Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., 1923, p. 485.

According to Thomsen⁷ the value of ΔH for this reaction is $-13,200$ cal. for $1 \text{ Au}_2\text{O}_3 (\text{Aq.})$ whence $\Delta S_{298} = (\Delta H - \Delta F)/T = (-13,200 - 19,100)/-298 = -108.4$ cal./mol./degree.

The writers wish to express their appreciation to Professor G. N. Lewis, who suggested this investigation.

Summary

1. Measurements have been made on the cell: $\text{H}_2(\text{g})$, $\text{H}_2\text{SO}_4(\text{x-M})$, $\text{Au}_2\text{O}_3(\text{s})$, $\text{Au}(\text{s})$, at three concentrations of sulfuric acid and at 25° . The electromotive force is seen to be substantially independent of concentration of sulfuric acid, the general average value being 1.364 ± 0.001 volts.

2. The free energy of formation of auric oxide from its elements, its dissociation pressure, and entropy of formation at 298°A. are calculated, all of which indicate that auric oxide is a very unstable compound.

TUCSON, ARIZONA

NOTES

Confirmatory Test for Aluminum.—The test suggested is a modification of that proposed by Attack.¹ It has the advantage that the reagent need not be freshly prepared each time. Further, the color absorption is greater.

The reagent consists of a saturated solution of alizarin in concd. acetic acid.

After separating the aluminum hydroxide from any chromium and zinc, it is washed, dissolved in hydrochloric acid and then reprecipitated with a slight excess of ammonium hydroxide. To this solution is added one drop of the alizarin reagent which imparts an apple-blossom pink coloration to the aluminum hydroxide. The latter will soon settle out, leaving the solution above colorless.

Plastic Films and the Drop-Weight Method of Interfacial Tension Measurement.—The drop-weight method of measuring surface and interfacial tensions has in recent years been greatly refined by Harkins and his co-workers.¹ Not only have they improved the apparatus in a

¹ Harkins and Brown, *THIS JOURNAL*, 41, 499 (1919).

mechanical sense but they have also shown that the law of Tate does not apply strictly, since the shape of the drop has an important effect upon the size of each drop, and therefore upon the number of drops formed from a given volume of liquid. It has been found that for reversible conditions a satisfactory correction for the shape effect can be made if the radius of the tip and the size of the drop formed are known.

In view of the importance of the shape development of the drops it is interesting to consider the possible effects of plastic film formation.

The work of Wilson and his students² is illuminating in regard to the thickness and mechanical properties of such films. They have determined that the surface films (solid or jelly?) formed by sodium stearate on its aqueous dispersions may attain a thickness of 10 to 40 microns³ and that such films exhibit frictional or plastic characteristics.⁴ They also very cleverly demonstrated that a solution of saponin (1 to 1000) with Nujol or castor oil gives an interfacial film exhibiting distinct frictional qualities.⁵ Holmes⁶ also discusses the mechanism of the building up of thick solid films and describes a very thick film formed between water and a benzene dispersion of gum dammar. Bancroft⁷ states that by adding salt to a soap solution the soap film can be made to come out so brittle that it will not form a satisfactory emulsion of oil in water. He believes that for good emulsification the film formed must be tough and elastic.

The above references are sufficient to show that one must consider the possibility of interfacial films being thick and either plastic and tough, or brittle. Plasticity, of course, connotes resistance to flow under low shear.

It has been commonly assumed that plastic films, if developed during the formation of a drop suspended from a dropping tip, would increase the drop size and the apparent interfacial tension. This assumption has as its corollary that plastic films can never be the cause of low apparent interfacial tensions. Is such an assumption justified? I believe not.

If a plastic film is formed around a partially developed drop the effect will be the same as though one had slipped a perfectly fitting casing of plastic material over the drop. If further solution tries to enter such an encased drop this plastic solid casing will resist distention and in order that the drop may increase its volume the body of the drop will be forced away from the dropping tip, thus tending to form an elongated drop.

⁷ Bancroft, "Applied Colloid Chemistry," McGraw-Hill, New York, 1926, p. 352.

Since this elongated drop is formed as the result of a mechanical constriction and the increased surface is not in harmony with the volume of the drop and the interfacial tension, the chances for the drop to snap off before reaching full development are very good.

In extreme cases, that is, in cases in which the interfacial film is both rapidly formed and very tough, the elongated drop shape will be stabilized, as in the case of the drop shown in Wilson's Fig. 18. Another complication which may well arise is the actual adhesion of such a film to the dropping tip. Harkins seems to have had this in mind in referring to a determination⁸ in which he obtained an "interfacial tension" of 0.04 dyne/cm. by dropping water containing 0.1 *M* sodium hydroxide and sodium chloride into benzene containing 0.1 *M* oleic acid. He states (p. 77) "In this case a solid film forms, and this causes the drops to hang longer than usual, but the minute value of the tension indicates that the tensile strength of the film is very low." As pointed out above, the "minute value" of the "interfacial tension" may mean that the film is strong and prevents the development of the drop. McBain and Burnett⁹ emphasize the tendency for the formation of solid soap curds when salt is present in a soap solution; it is likely that solid films were formed in the case of other determinations reported in Harkins' paper. It would be interesting to know the magnitude of the deviation of individual determinations from the reported mean in the case of certain of these determinations. The check data given on p. 79 are either misprinted or reveal a deviation of 50% among check determinations.

To return to the non-equilibrium "interfacial tension" which Harkins reports as 0.04 dyne/cm. it is worth while to consider, first, the conditions at this "interface" and, second, the definition of interfacial tension. Starting from the inside of the drop we have (1) aqueous solution, (2) interface between aqueous solution and solid soap phase, (3) solid soap phase, (4) interface between solid soap phase and benzene dispersion of fatty acid. *If the solid soap phase touches the dropping tip, there will be no liquid liquid-interface.* The soap film is solid; it will resist distention and will crinkle if the drop tends to grow smaller.

If the soap film does not touch the tip, there will be a true liquid liquid-interface next the tip, but not elsewhere.

Interfacial tension as defined by Willows and Hatschek¹⁰ involves only reversible forces, the stress per cm. being independent of the size of the surface. Clearly, if a plastic solid film touches the dropping tip and completely surrounds the drop there can be no interfacial tension.

⁸ Harkins and Zollman, *THIS JOURNAL*, **48**, 69 (1926).

⁹ McBain and Burnett, *J. Chem. Soc.*, **121**, 1332 (1922).

¹⁰ Willows and Hatschek, "Surface Tension and Surface Energy," P. Blakiston's Son and Co., Philadelphia, 1923, p. 2.

Measurements made under conditions which make it probable that such a condition existed during the determinations should not be reported as "interfacial tensions," because they can in no way satisfy the fundamental requirement of reversibility.

In case the plastic film merely approaches but does not touch the tip, a true liquid liquid-interface will exist next the tip and the plastic film can only affect the results by influencing the shape development of the drop. Since the correction factor, which is dependent upon the shape development, varies from 1.3 to 1.8, it seems conservative to state that it is impossible to ignore any condition or set of conditions which is capable of affecting this shape development.

The Purification of Toluene for Thermo-Regulators.—For use in a mercury-toluene thermo-regulator the toluene must be free from traces of certain impurities, notably sulfur compounds, which will foul the surface of the mercury and interfere with the sharp adjustment of the regulator. According to Vanino,¹ toluene may be purified by washing it repeatedly with sulfuric acid, then with water until the washings are neutral to litmus paper, and finally drying the toluene over metallic sodium.

A quantity of c. p. toluene purified according to Vanino's directions was still found to corrode the mercury. It occurred to us to determine the effect of sodium amalgam. The toluene was accordingly boiled under a reflux condenser with sodium amalgam containing 1% of sodium. The toluene was then decanted, washed with water and finally distilled. The water remaining in the toluene was all removed with the first small fraction of the distillate, which was accordingly rejected.

The toluene purified in this manner has been in use for several months without showing any action upon the surface of the mercury.

METALLIC SALTS OF LOPHINE, 1,2,4-TRIAZOLE AND TETRAZOLE

BY HAROLD H. STRAIN

RECEIVED JANUARY 27, 1927

PUBLISHED AUGUST 5, 1927

Introduction

When negative groups are substituted for one or two hydrogen atoms of a molecule of ammonia, a compound is obtained which is related to ammonia as the familiar oxygen acids are related to water. Such ammonia derivatives must therefore be regarded as acids of an ammonia system of compounds,¹ and in order to distinguish them from the oxygen or aquo acids, Franklin has called them ammono acids. A number of these ammono acids are known; for example, hydrocyanic acid or ammono carbonous acid, cyanamide or ammono carbonic acid, benzamidine or ammono benzoic acid, etc.

In general, the ammono acids are much weaker than the corresponding aquo acids, as shown by the inability of many of them to form metallic salts in the presence of water. However, by carrying out reactions in liquid ammonia, a poorer solvolytic solvent than water, Franklin² has shown that it is possible to prepare metallic salts of the very weak ammono acids pyrrole, indole and carbazole.

The ammono acids just mentioned owe their acid properties to the negative influence of the doubly bonded carbon atoms. Now, since nitrogen is a more electronegative element than carbon, it seems reasonable to expect that the acid properties of a compound such as pyrrole would be accentuated by substituting a nitrogen atom for a CH-member of the ring, while further substitution by nitrogen atoms would produce still stronger acids. Accordingly, pyrrole,

imidazole, $\begin{array}{c} \text{CH}=\text{CH} \\ | \qquad \qquad \qquad \diagup \\ \text{CH}=\text{CH} \end{array} \text{NH}$; 1,2,4 triazole, $\begin{array}{c} \text{CH}=\text{N} \\ | \qquad \qquad \qquad \diagup \\ \text{N}=\text{CH} \end{array} \text{NH}$; and tetrazole, $\begin{array}{c} \text{CH}-\text{N} \\ | \qquad \qquad \qquad \diagup \\ \text{N}=\text{N} \end{array} \text{NH}$ should be am-

mono acids, their strength increasing in the order given. Furthermore, alkyl and aryl derivatives of the above compounds should be acids, providing one hydrogen atom remains attached to a nitrogen atom, the strength of the resulting acid being dependent upon the negative character of the substituted group. Thus, lophine, triphenylimidazole,

$\begin{array}{c} \text{C}_6\text{H}_5\text{C}-\text{N} \\ || \qquad \diagup \\ \text{C}_6\text{H}_5\text{C}-\text{NH} \end{array} \text{CC}_6\text{H}_5$, should be a stronger acid than imidazole.

¹ Franklin and Stafford (a) *Am. Chem. J.*, **28**, 83 (1902); (b) Franklin, *Eighth Int. Cong. App. Chem.*, **6**, 119 (1912); (c) *THIS JOURNAL*, **37**, 2279 (1915); (d) **46**, 2137 (1924).

² Franklin, *J. Phys. Chem.*, **24**, 81 (1920).

Since, formally at least, the nitrogen compounds just mentioned are ammonio acids, they should react with the more electropositive elements and their amides to form salts^{1a,c} if the reactions be carried out in a poor solvolytic solvent such as ammonia. These compounds should also show conductivities characteristic of weak acids when dissolved in liquid ammonia.

The following experiments show that imidazole, lophine, triazole and tetrazole react with sodium, calcium and magnesium and with the amides of lithium, sodium, potassium, copper and silver, forming salts, while conductivity measurements indicate that the strength of the acid is dependent upon the negative character of the components of the molecule.

Unless otherwise stated, all salts were prepared in liquid ammonia solution. The methods of manipulation, such as handling the liquid ammonia, drying the salts, determining the ammonia of crystallization and preparing the salts for analysis, were essentially the same as those previously described by Franklin.³ All the salts thus prepared were unstable in the presence of water, being hydrolyzed to the acid and to the metallic hydroxide.

Metallic Salts of Imidazole

Imidazole dissolves abundantly in liquid ammonia, forming a clear solution from which the imidazole may be obtained by evaporation of the solvent, there being no formation of an ammonium salt. Wenzel,⁴ working in this Laboratory, found that imidazole in ammonia solution attacks magnesium slowly, setting hydrogen free and forming a slightly soluble magnesium salt. Wenzel has also prepared the potassium, sodium, calcium and silver salts of imidazole. However, Wyss⁵ had previously prepared the silver salt.

Metallic Salts of Lophine

Lophine, prepared by heating hydrobenzamide,⁶ is only slightly soluble in liquid ammonia at room temperature, while at -35° it is practically insoluble. Lophine does not form an ammonium salt.

Metallic Salts of 1,2,4-Triazole

Preparation of Triazole.—According to Pellizzari,⁷ two molecules of formamide distilled with one molecule of hydrazine hydrochloride form 1,2,4-triazole in poor yields. Substitution of hydrazine sulfate for hydrazine hydrochloride did not increase the yields. It was found, however, that a yield amounting to one-sixth of the theoretical could be

^a The abbreviations used in this table are: M., metal; N, nitrogen; sol., soluble; sl., slightly; m., moderately; v., very. The percentage compositions of these compounds are all based on the anammonous (dry) salts.

^b Magnesium and calcium lophine react with liquid ammonia, forming ammonio basic salts as indicated by the high nitrogen analyses. If a reducing agent is present, these salts form highly red-colored solutions.

^c The calcium salt was prepared by the action of lophine on a solution of metallic calcium in liquid ammonia and by the action of lophine on calcium amide.

^d Prepared by the action of lophine on potassium amide.

^e Prepared by the action of lophine on silver amide and by the action of potassium lophine on silver nitrate.

^f Prepared by treating a solution of cupric nitrate with potassium lophine. The vapor pressure of the ammonated salt did not reach a constant value, hence the ammonia of crystallization could not be accurately determined.

^g Prepared by treating cuprous amide with lophine.

^h Prepared by the action of lophine on lithium amide.

ⁱ Prepared by the action of lophine on sodium amide.

obtained by adding two molecules of finely divided potassium hydroxide to the above mixture and allowing it to dissolve completely before distilling.

The distillation was made in a Pyrex flask over a luminous flame, while the distillate was collected in a balloon flask cooled in an ice-and-salt mixture. The semi-solid condensate was extracted with boiling ethyl acetate from which the triazole separated upon cooling. The crystals, after recrystallization from alcohol, melted at 120–121°.

Triazole is very soluble in liquid ammonia, forming a clear solution. Upon evaporation of the solvent, crystals of triazole are obtained, thus showing that triazole does not form an ammonium salt.

Until the following preparations were made, cupric triazole was the only metallic salt of triazole known. It was prepared by Pellizzari and Cuneo⁸ as a blue precipitate when triazole was added to a neutral or slightly alkaline aqueous solution of a copper salt.

TABLE II
SALTS OF 1,2,4-TRIAZOLE^a

	CuC ₂ H ₂ N ₃ ·XNH ₄						
	CuC ₂ H ₂ N ₃						

^a Since the salts were removed from the reaction tubes in aqueous solution, the Kjeldahl method for the determination of nitrogen was the only one which was applicable. However, it was found that unchanged triazole escapes with the vapors of the acid; hence, no nitrogen determinations were made. The analytical results are based on the anammonous salts.

^b Prepared by the action of triazole on sodium amide.

^c Prepared by the action of triazole on silver amide.

^d Prepared by the action of triazole on magnesium.

^e Prepared by treating a solution of calcium in liquid ammonia with triazole.

^f Prepared by the action of triazole on cuprous amide.

Metallic Salts of Tetrazole

The tetrazole used in the following preparations was made from its carboxylic acid which was prepared according to the method of Oliveri-Mandalá and Passalacqua.⁹ After the tetrazole had been recrystallized thrice it was deemed sufficiently pure.

Tetrazole is sufficiently acidic so that many of its salts have been pre-

pared in aqueous solution. Thiele and Ingle¹⁰ have reported the sodium and barium salts, Bladin¹¹ has prepared the silver and copper salts, while Bauer¹² has measured the electrical conductivity of aqueous solutions of free tetrazole.

Ammonium Tetrazole, NH_4CHN_4 .—Tetrazole reacts with gaseous ammonia, forming the ammonium salt which is fairly soluble in liquid ammonia. This salt was analyzed by distilling the ammonia from a dilute aqueous solution made alkaline with sodium hydroxide.

Anal. Calcd. for NH_4CHN_4 : NH_3 , 19.8. Found: 19.5.

Calcium Tetrazole, $\text{Ca}(\text{CHN}_4)_2$.—Tetrazole was allowed to react with metallic calcium in liquid ammonia solution. The blue color due to the calcium was rapidly dispelled, a quantity of hydrogen almost equivalent to the amount of metal used was rapidly evolved, while long, needle-like crystals were obtained by concentrating the solution.

A second preparation of this salt was made by treating calcium amide with tetrazole, the calcium being determined as oxalate.

Anal. Calcd. for $\text{Ca}(\text{CHN}_4)_2$: Ca, 22.2. Found: Ca, 21.8.

Conductivity Measurements

The electrical conductances of ammonia solutions of pyrrole, imidazole, triazole and tetrazole¹³ were measured in an apparatus similar to that described by Elsey.¹⁴ Lophine is so insoluble in ammonia that a sufficiently concentrated solution could not be obtained for accurate measurements.

In Table III the dilution is given in liters per mole. The values of the equivalent conductivity in Kohlrausch units were obtained by interpolation of the curves plotted from the conductivity measurements.

TABLE III
EQUIVALENT CONDUCTIVITIES OF SOLUTIONS OF PYRROLE, IMIDAZOLE, TRIAZOLE AND
TETRAZOLE IN LIQUID AMMONIA

Dilution $\Phi \times 10^{-3}$	8	16	32	64	128	256	512	1024	2048	4096	8192

¹² Bauer, *Ann.*, **287**, 249 (1895).

¹³ The pyrrole used in measuring the conductivity was purified according to the method of Ciamician and Dennstedt [*Ber.*, **19**, 173 (1886)]. The imidazole, which was contributed by Wenzel and which he had purified by distillation, was recrystallized from toluene. The triazole and tetrazole were obtained sufficiently pure by recrystallizing portions of the specimens used in preparing the metallic salts.

¹⁴ Elsey, *THIS JOURNAL*, **42**, 2454 (1920).

The author wishes to take this opportunity to express his sincere thanks to Dr. E. C. Franklin, at whose suggestion and under whose careful and kindly direction this investigation was carried out.

Summary

Any compound which is derived from ammonia by substituting negative groups for one or two of the three hydrogen atoms is an ammono acid.

The strength of the ammono acids is dependent upon the negative character of the components of the molecule; thus, the acidity of pyrrole, imidazole, triazole and tetrazole increases in the order given as shown by the conductivity measurements.

A number of the metallic salts of the ammono acids lophine, triazole and tetrazole have been prepared.

ESTABLISHMENT OF THE OPTIMAL HYDROGEN-ION ACTIVITIES FOR THE ENZYMIC HYDROLYSIS OF STARCH BY PANCREATIC AND MALT AMYLASES UNDER VARIED CONDITIONS OF TIME AND TEMPERATURE¹

BY H. C. SHERMAN, M. L. CALDWELL AND MILDRED ADAMS

RECEIVED MARCH 25, 1927

PUBLISHED AUGUST 5, 1927

The development of our investigation of the amylases and related enzymes makes it important now to know, and to be able experimentally to establish and maintain, the reaction most favorable to the activity of each enzyme under investigation throughout a wider range of time and temperature than is involved in the determination of the so-called diastatic powers, for which conditions only had optimal hydrogen-ion activities been established in the course of the earlier work of this Laboratory.

Experiments were therefore undertaken to establish the optimal hydrogen-ion activities for malt and pancreatic amylases when the temperature and time of enzymic hydrolysis were varied. The data obtained are discussed briefly below.

Experiments and Discussion

The experimental methods of measuring amylase activity have been described in detail in previous papers from this Laboratory.²

The slight reducing action of the substrate without enzyme was measured for each of the times, temperatures and hydrogen-ion activities

¹ We are greatly indebted to the Carnegie Institution of Washington for grants in aid of this investigation.

² Sherman and co-workers, *THIS JOURNAL*, 41, 231 (1919); 32, 1073 (1910); 42, 2461 (1921); 37, 623 (1915).

studied, and used as a correction in reporting the enzymic activities. The hydrogen-ion activities reported in this paper were determined electrometrically in portions of the actual substrate systems used.

Malt Amylase in the Presence of Phosphates.—The experiments with malt amylase were carried out both with extracts of barley malt prepared in a uniform manner and with a purified preparation which had been obtained according to the method of Sherman and Schlesinger and these two forms of the enzyme gave essentially concordant results. In the earlier series of these experiments, the enzyme was allowed to act upon starch solutions containing 0.06 *M* dihydrogen phosphate and adjusted to a systematic series of Sørensen values at close intervals from *P_H* 4.0 to *P_H* 6.0. The time was varied from one-half hour to two hours and the temperature from 30 to 70°. These experiments showed that as the temperature of the hydrolysis is increased, malt amylase becomes more sensitive to changes in the hydrogen-ion activity of its environment. Also the enzyme exerted its optimal activity in less acid solutions as the temperature of the hydrolysis was increased. Thus malt amylase exerted its optimal activity under the conditions of these experiments in solutions adjusted at room temperature to Sørensen values of *P_H* 4.4 to 5.0 at 30 and 40°; of 4.6 to 5.0 at 50°; of 5.2 to 5.5 at 60° and of 5.3 to 5.8 at 70°. With the purified preparation the zone of optimal activity was slightly narrower, *P_H* 4.6 to 4.8 at 40° and 5.3 to 5.4 at 60°.

At any given temperature, however, malt amylase exerts its activity under practically the same optimal conditions when the period of hydrolysis is varied from one-half to two hours.

Between the completion of this part of our experimental work and its preparation for publication, Olsen and Fine³ published the results of experiments with a mixture of wheat and malted barley flours in which also it was found that the enzyme exerts its optimal activity at different hydrogen-ion activities according to the temperature, and noted a greater influence of small changes of hydrogen-ion activity at the higher temperatures.

Electrometric Measurements at Temperatures of Enzyme Experiments.—The electrometric measurements of the solutions so far considered were made at room temperature and calculated with the usual temperature corrections to Sørensen or *P_H* values.⁴ As shown above, these values were found to differ markedly for those solutions which enable malt amylase to exert its optimal activity at the different temperatures. The question therefore arose as to whether the hydrogen-ion activities of the starch solutions measured at room temperature are also the hydrogen-

³ Olsen and Fine, *Cereal Chemistry*, 1, 215 (1924).

⁴ Clark, "The Determination of Hydrogen Ions," Williams and Wilkins, Baltimore, 1923, 2nd ed., pp. 457, 459.

ion activities of the solutions during hydrolysis. To answer this question e.m.f. measurements were made at the higher temperatures as well as at room temperature upon starch solutions (substrate systems) made up exactly as were those which had been found to afford the most favorable conditions for the amylase activity at each temperature. The P_H values were calculated according to the equation e.m.f. (saturated calomel) — e.m.f. (obs.) = $0.000198T \log(C_{H^+}/10^{-4.72})$, where $0.000198T \log(C_{H^+}/10^{-4.72})$ is the electrode potential for hydrogen at atmospheric pressure⁵ and where 0.5266 is⁶ the e.m.f. of the saturated calomel cell at 25°. The calomel cell was of the type described by Wilson and Kern⁷ and could not conveniently be immersed in the thermostat. There would, therefore, be a slight Peltier effect which would cause some error in the above calculations but which would not be significant in the changes in which we are interested here. The e.m.f. observed was corrected for barometric pressure by use of the equation,⁴ $E_{\text{bar.}} = (0.000198T/2) \log(760/x)$, where x is the barometric pressure minus the vapor pressure of water at the temperature under consideration. This correction was added to the observed e.m.f. in the above equation.

The results are given in Table I and show that the e.m.f. and Sørensen values obtained with a given solution measured at the lower and higher temperatures are not markedly different and that the measurements made at room temperature are also a measure of the hydrogen-ion activities of the substrates at the temperatures of hydrolysis. This would seem to indicate that malt amylase exerts its optimal activity under different conditions of hydrogen-ion activity at different temperatures.

Malt Amylase in the Presence of Acetate-Acetic Acid Mixtures.—In view of the work of Chrzaszcz, Bidzinski and Krause⁸ and of the more

⁵ Fales, "Inorganic Quantitative Analysis," The Century Co., New York, 1925, p. 257.

⁶ Fales and Mudge, *THIS JOURNAL*, **42**, 2434 (1920).

⁷ Wilson and Kern, *Ind. Eng. Chem.*, **17**, 74 (1925).

⁸ Chrzaszcz, Bidzinski and Krause, *Biochem. Z.*, **160**, 155 (1925).

recent work of Luers and Nichimura,⁹ we have carried out a second series of experiments with malt amylase under the same conditions described for the first series, except that we used 0.01 *M* sodium acetate-acetic acid buffer mixtures instead of phosphate to regulate the hydrogen-ion activities of the substrates. It was found that in the presence of acetate and in experiments of the same duration, malt amylase exerts its optimal activity at 40° and at 60° in solutions of about *P_H* 4.6 for half an hour and at about *P_H* 4.8 for two-hour periods of hydrolysis. This confirms the findings of Luers and Nichimura and indicates that the effects of acetate and phosphate are somewhat different in this respect. The enzyme is more sensitive to changes in the hydrogen-ion activity of its environment at the higher temperature, whether it acts in the presence of phosphate or of acetate, but in the presence of acetate there is a tendency for the optimal enzymic activity to occur in slightly less acid solutions as the experimental period is lengthened.

Within the range covered by our experiments, heat does not appreciably influence the hydrogen-ion activities of our systems. This is shown for the phosphate solutions by the experiments summarized in Table I and has also been experimentally demonstrated for the acetate solutions. Thus the e.m.f. value of the starch solution, containing 0.01 *M* acetate, which permitted malt amylase to exert its optimal activity at 60° was 0.5215 (or *P_H* 4.65) when measured at 23.5° and 0.5240 (or *P_H* 4.72) when measured at 60°, the temperature of the hydrolysis.

Parallel hydrolyses of the phosphate and acetate substrates carried out at 60°, with determinations of the hydrogen-ion activities of the solutions before and after the hydrolyses, showed that neither of the solutions had changed in hydrogen-ion activity during the experiment.

Pancreatic Amylase.—Experiments similar to those described with malt amylase were also carried out with pancreatic amylase, measuring both its saccharogenic and amylolytic activities. Starch solutions, two per cent. for the former and one per cent. for the latter measurements, were adjusted to Sørensen values systematically varied at close intervals from *P_H* 6.3 to *P_H* 7.7. The enzymic activity was measured in periods of one-half, one and two hours at 30 to 70°.

In the first series of experiments, a commercial pancreatin was used in the presence of 0.05 *M* sodium chloride and 0.0005 *M* disodium phosphate. In the second series of experiments a purified enzyme preparation obtained according to the method of Sherman and Schlesinger was used in the presence of 0.03 *M* sodium chloride and 0.01 *M* phosphate mixtures which had very recently been found¹⁰ to afford slightly more satisfactory conditions.

⁹ Luers and Nichimura, *Wochenschrift für Brauerei*, 43, No. 38, p. 415-416, Sept., 1926.

¹⁰ Adams, *Dissertation*, Columbia University, 1927.

The results of the two series of experiments are in agreement and show that under these conditions the hydrogen-ion activities for the optimal enzymic activity expressed as Sørensen values were P_H 7.0 to P_H 7.2 for one-half to two hours at 30 to 50°, P_H 6.9 for half an hour and P_H 6.7 for two-hour periods at 60°. The rapid destruction of the enzymic activity at 70° made it difficult to obtain any satisfactory results at this temperature.

This difference between the hydrogen-ion activities for the optimal activity of pancreatic amylase at the lower temperatures and at 60°, while very slight, appears to be a true difference and not due to the influence of heat on the hydrogen-ion activities of the solutions themselves, for the hydrogen-ion activity of the solution affording optimal enzymic activity at 60° was found to be the same when measured at room temperature and at 60°.

Summary

As the temperature of hydrolysis is increased from 30 to 70°, malt amylase exerts its optimal activity at different hydrogen-ion activities when acting in the presence of 0.06*M* phosphate mixtures; whereas, in the presence of 0.01*M* acetate-acetic acid mixtures, this amylase exerts its optimal activity in solutions of the same hydrogen-ion activity at the different temperatures.

In the presence of 0.06 *M* phosphate, the hydrogen-ion activities of the solutions affording optimal activity of the enzyme did not show appreciable change as the experimental period was lengthened from one-half to two hours at any given temperature (within the range 30–60°) while in the presence of 0.01 *M* acetate there is a tendency for the enzyme to exert its optimal activity in slightly less acid solutions as the period of hydrolysis is increased.

The difference in the behavior of the enzyme in the presence of phosphate and of acetate has been shown by e.m.f. measurements of the solutions at room temperature and at the temperatures of hydrolysis, and by measurements before and after hydrolysis, not to be due to the influence of heat or of the products of hydrolysis upon the hydrogen-ion activities of the solutions themselves.

Whether in the presence of phosphate or of acetate, a higher temperature seems to render malt amylase more sensitive to changes in the hydrogen-ion activity of its environment.

Pancreatic amylase, in experiments of one-half to two hours at 30–50°, exerted its optimal activity at P_H 7.0–7.2; but in experiments at 60° the optimal activity for half-hour periods was found at P_H 6.9 and for two-hour periods at P_H 6.7.

From the standpoint of accurate investigation of enzyme action, the results here reported upon two typical amylases indicate that the factors

which induce optimal enzymic activity are even more dependent upon each other than has previously been realized and that none of them should be regarded as fixed if any of the others is changed.

CATALYTIC OXIDATIONS IN AQUEOUS SOLUTIONS

I. THE OXIDATION OF FURFURAL

BY NICHOLAS A. MILAS¹

RECEIVED MARCH 29, 1927

PUBLISHED AUGUST 5, 1927

Introduction

The present investigations are part of the applications of catalysts such as osmium tetroxide, vanadium pentoxide, etc., to the oxidation of organic compounds by means of chlorates.

In previous communications² it has been shown that small quantities of osmium tetroxide can induce the oxidation of relatively large quantities of organic substances by means of chlorates. The use of vanadium pentoxide with chlorates has been heretofore limited only to a very few special cases³ in which vanadium salts were used rather than the oxide in the presence of strong acids. The present paper describes several experiments in which vanadium pentoxide has been successfully used in neutral as well as in dilute acid solutions to induce the oxidation of furfural and pyromucic acid by means of chlorates.

Furfural has been oxidized with dil. potassium permanganate solution to pyromucic acid by Volhard,⁴ with bromine water at the temperature of the water-bath to mucobromic acid by Simonis,⁵ with hydrogen peroxide in the presence of ferrous salts to δ -hydroxyfurfural by Cross, Bevan and Heiberg,⁶ and with Caro's acid to succinic acid by Cross, Bevan and Briggs.⁷

In the Experimental Part, it will be shown that with a mixture of sodium chlorate and small quantities of osmium tetroxide in dilute acid solution, furfural yields principally mesotartaric acid, while fumaric acid is the chief product formed when the reaction is carried out in neutral solution with osmium tetroxide replaced by vanadium pentoxide. Similar results

but lower yields of the principal products were obtained when pyromucic acid was used instead of furfural.

These results are not at all surprising but quite in accordance with the classical researches of Hill and his co-workers on the structure of the furane ring. Hill and Sanger⁸ have shown that pyromucic acid is slowly oxidized with bromine water first to fumaryl aldehyde, then at low temperatures to maleic acid or, at higher temperatures, to fumaric acid. More striking results were obtained by Hill and Hartshorn⁹ who found that α,δ -dibromofurane, prepared from δ -bromopyromucic acid, oxidizes to give, in the cold, maleic acid and at higher temperatures fumaric acid, hydrogen bromide being given off in both cases. Obviously hydroxylation of the conjugated system of the furane ring occurred first on the α,δ -carbon atoms followed by splitting of hydrogen bromide and subsequent hydrolysis of the maleic anhydride. At higher temperatures hydrolysis of maleic anhydride and transmutation of maleic acid to fumaric acid may occur simultaneously.

A similar mechanism may be adopted to explain the catalytic oxidation of furfural. Although no pyromucic acid was isolated, furfural must first be oxidized to this acid. In the reactions studied, there are two distinct stages of each reaction, a violent followed by a mild reaction. This is particularly true in the oxidation of furfural with vanadium pentoxide and sodium chlorate in which the temperature rises during the violent reaction from 70 to 105°. Furthermore, carbon dioxide is evolved in greater quantities during the violent stage. In addition to the temperature effect in this last case, considerable quantities of chlorine dioxide are formed, which are responsible for the transmutation of maleic acid as

⁸ Hill and Sanger, *Proc. Am. Acad.*, **21**, 144 (1885-6).

⁹ Hill and Hartshorn, *Ber.*, **18**, 448 (1885).

soon as it is formed. This view has been substantiated by actual experiments in which maleic acid was transmuted, in aqueous solution, to the extent of 10% in eight hours at 70 to 75° by the mixture of vanadic oxide and sodium chlorate. The mechanism of the principal reactions, therefore, might be best expressed as shown on the preceding page.

This mechanism seems, to the author, the most probable, although other mechanisms are possible. So far, attempts to isolate the dihydroxypyromucic acid failed, due perhaps to its extreme instability. However, maleic acid aldehyde has been actually isolated as the intermediate product of the reaction. Several investigators have already shown that when pyromucic acid is carefully oxidized in water or alkaline solution with bromine,¹⁰ or with oxygen¹¹ in presence of light, maleic acid aldehyde is formed.

Experimental Part

Oxidation of Furfural with Sodium Chlorate and Vanadium Pentoxide

Materials Used.—Two grades of furfural were used, the c. p. grade and the technical grade, both furnished by the Eastman Kodak Company.

The sodium chlorate used was the u. s. p. grade furnished by Merck.

Preparation of the Catalyst.—Twenty g. of c. p. ammonium metavanadate was suspended in 200 cc. of water and to this was added slowly 30 cc. of concd. hydrochloric acid (d., 1.90). The reddish-brown semi-colloidal precipitate was washed several times with water by decantation and finally suspended in 300 cc. of water and allowed to stand at room temperature for three days. This treatment made the precipitate almost granular and easy to filter. The precipitate was then collected on filter paper by means of the pump, washed several times to free it from hydrochloric acid and dried for 12 hours at 120°. To free it completely from occluded hydrochloric acid, it was finely powdered and dried again at 120° for 12 hours longer; yield of the dried oxide, 11 g. The catalyst thus prepared is very active for all purposes of oxidations with chlorates.

The Reaction.—Preliminary experiments showed that sodium chlorate in aqueous solution without the aid of the catalyst does not oxidize furfural even if the solution is made acid or heated to the boiling point of water. However, vanadium pentoxide in the absence of chlorate oxidizes furfural and shows the following changes of color:¹² V_2O_5 (yellow) $\rightarrow V_2O_4$ (blue) $\rightarrow V_2O_3$ (green). These color changes are instantly reversed when a small crystal of chlorate is added to the solution and reappear when

¹¹ Ciamician and Silber, *Ber.*, 46, 1563 (1913).

¹² T. F. Rutter [*Dissertation*, Leipzig, 1904] has shown that salts of vanadium tetroxide are blue and those of vanadium trioxide are green.

the chlorate is completely reduced to the chloride. Ordinarily, when chlorate is present in excess, vanadium pentoxide does not undergo the above color changes and the reaction appears to take place entirely on its surface. As the acidity of the solution rises, due to the organic acids produced as a result of the oxidation, vanadium pentoxide goes slowly into solution and is held there, perhaps in the colloidal state. One therefore may easily conceive that vanadium pentoxide acts as an "oxygen carrier" in inducing the oxidation of organic compounds by means of chlorates.

The general procedure as finally adopted was as follows.

Forty-six g. of sodium chlorate, 0.2 g. of vanadium pentoxide and 100 cc. of water were placed in a 500cc. Erlenmeyer flask which was connected to a condenser and a dropping funnel with a two-hole rubber stopper. The mixture was heated to 70–75° by supporting the flask 10 cm. above a hot electric plate. This arrangement was very satisfactory in keeping the temperature constant to within 3°. Twenty g. of furfural was then slowly dropped into the solution at the rate of about 0.5 g. per minute, and allowed to undergo the violent reaction. During this reaction the temperature of the solution rises to 105° and a rapid evolution of carbon dioxide takes place. If the addition of furfural is too rapid the reaction becomes too violent and almost uncontrollable; if it is too slow the fumaric acid formed is further oxidized to oxalic acid and thence to carbon dioxide and water. The violent reaction lasts from 50 to 75 minutes. At the end of a definite number of hours, the reaction was stopped, the flask disconnected, stoppered and allowed to stand at room temperature overnight. The fumaric acid which separated was collected on the filter paper, washed once with cold water, dried and weighed. This acid is fairly pure; m. p., 282–284° in a sealed tube. After one recrystallization from hot water, the melting point rose to 285–287° and remained unaltered on further recrystallizations.

Anal. Subs., 0.2881: CO₂, 0.4342; H₂O, 0.0910. Calcd. for C₄H₄O₄: C, 41.37; H, 3.44. Found: C, 41.11; H, 3.51.

Titration with sodium hydroxide. Subs., 0.2606, 0.1957; required 43.54, 32.50 cc. of 0.1037 *N* NaOH (phenolphthalein). Calcd. for C₄H₄O₄: 43.33, 32.52 cc.

The last two experiments of Table I show the influence of a 2% solution of sulfuric acid on the speed of the reaction as well as on the yield of fumaric acid. The reaction, however, is much too violent to be of practical use.

TABLE I
VARIATION OF YIELD OF FUMARIC ACID WITH TIME OF HEATING

Expt.	1	2	3	4	5 ^a	6 ^b	7 ^{a,b}
Time of heating, hrs.	22	16	12.5	7	8	4.5	3
Fumaric acid, yield, %	51.7	70.3	77.8	64.1	66.2	72.4	70.0

^a Technical furfural was used in these experiments.

^b The water used was replaced with 2% sulfuric acid.

It will be seen from Table I that the maximum yield of fumaric acid, assuming that all furfural is oxidized to this acid, was obtained when the reaction mixture was heated for 12.5 hours.

Treatment of the Filtrate.—The filtrate of Expt. 4 shown in Table I was boiled with an excess of barium carbonate for two hours, cooled, and then filtered by means of

the pump. The filtrate was treated with two volumes of 95% alcohol; a white, semi-granular precipitate formed. This was collected on the filter paper and dried at room temperature; yield, 9.3 g. Since this salt was more soluble in hot than in cold water, it was recrystallized twice from this solvent and dried in a vacuum desiccator over concd. sulfuric acid for several days.

Anal. Subs., 0.2873, 0.2132, 0.2812; BaSO₄, 0.2211, 0.1664, 0.2195. Calcd. for C₈H₂O₆Ba.H₂O: Ba, 46.2. Found: 45.32, 45.94, 45.95.

Determination of water. Subs., 0.4504, heated at 150–160° to constant weight; H₂O, 0.0241. Calcd. for C₈H₂O₆Ba.H₂O: H₂O, 6.05. Found: 5.36.

Combustion of the barium salt. Here the assumption is made that all barium is converted to barium carbonate and the percentage of carbon is calculated accordingly. Subs., 0.2745, CO₂, 0.1939; H₂O, 0.0365. Calcd. for C₈H₂O₆Ba.H₂O: C, 20.16; H, 1.36. Found: C, 19.57; H, 1.48.

The empirical formula of this acid, therefore, is C₈H₄O₆. Work is now in progress to determine its structure.

Isolation of Maleic Acid Aldehyde.—An experiment was then performed in the usual way except that it was stopped at the end of the violent reaction. The reaction mixture was cooled in ice and the solid which separated was dried and weighed; yield of fumaric acid, 6 g. The filtrate was shaken with 500 cc. of ether and the ether extract dried for several days over anhydrous sodium sulfate. When the ether was distilled the residue consisted of a mixture of a thick, brownish oil of a very penetrating odor and a whitish solid which proved to be fumaric acid. The oil is very unstable and decomposes when heated with water on the water-bath, to give fumaric acid. The ether extraction, however, is not efficient and the original aqueous solution was found to contain large quantities of maleic acid aldehyde, which gives a rich orange-reddish color in water when heated on the water-bath with a few drops of an alcoholic solution of phloroglucinol. The phenylhydrazone derivative of this aldehyde was then prepared as follows. The original aqueous solution was neutralized with sodium carbonate (litmus), cooled in ice and phenylhydrazine added in excess. A yellowish-brown precipitate was formed which became deep yellow upon the addition of dil. acetic acid. The precipitate was quickly removed from the solution mixture, dried and weighed; yield, 11 g. When recrystallized twice from hot benzene, it yielded crystals (needles under the microscope); m. p., with decomposition, 157.5–158°. Fecht^{10d} describes the same substance having a melting point of 158–159°.

Anal. Subs., 0.1297, 0.2295; N₂, 16.5 cc. (18°, 759 mm.), 28.6 cc. (18°, 759.5 mm.) (over 50% KOH).

Calcd. for C₁₀H₁₀O₂N₂: N, 14.74. Found: 15.04, 14.71.

Oxidation of Pyromucic Acid with Sodium Chlorate and Vanadium Pentoxide

Pyromucic acid was prepared according to Wilson.¹³ It was purified by recrystallization from a hot mixture of two parts of carbon tetrachloride and one part of chloroform, and melted at 132–133°.

Five g. of pyromucic acid, 9 g. of sodium chlorate, 0.08 g. of vanadium pentoxide and 25 cc. of water were brought together in a 250cc. Erlenmeyer flask which was connected to a reflux condenser. The mixture was heated at 70–75° for eight hours, then cooled and the solid, 3.5 g., separated and dried. Since this appeared to be a mixture of unoxidized pyromucic and fumaric acids, it was treated with a small volume of ether,

¹³ Wilson, "Organic Syntheses," John Wiley's Sons and Co., 6, 44, (1926).

which extracted the former. The residual solid was recrystallized twice from hot water; m. p., 284 to 286° in a sealed tube; yield, 1 g. The presence of small quantities of oxalic acid was detected in the original mixture by the calcium oxalate test, but no attempt was made to isolate any other acid.

Oxidation of Furfural with Sodium Chlorate and Osmium Tetroxide

The catalyst was prepared according to Milas and Terry.^{2a} Preliminary experiments showed that osmium tetroxide, without the presence of chlorates, oxidizes furfural and forms a dark film of one of its lower oxides which adheres to the furfural and is not readily reoxidized by the addition of a solution of sodium chlorate. An experiment run continuously for a week at 50° in a thermostat failed to show an appreciable diminution of volume of the furfural layer. However, when the water used was replaced with an equivalent volume of a solution of 0.1 *N* hydrochloric acid furfural was oxidized, at first rapidly, then slowly to mesotartaric and oxalic acids. The following procedure was finally adopted.

Fifty-five g. of sodium chlorate, 10 cc. of a 0.98% solution of osmium tetroxide, 260 cc. of water and 30 cc. of about a 1 *N* solution of hydrochloric acid were brought together in a 500cc. Erlenmeyer flask connected to a reflux condenser and a dropping funnel. The mixture was brought to 50° in a thermostat, then 20 g. of pure furfural was dropped into it at the rate of about 5 cc. for every 30 minutes. The solution was heated until the odor of furfural had almost completely disappeared. This took 110 hours. At the end of this period of time, the solution was cooled and shaken with 200 cc. of benzene to extract the catalyst. The water layer contained tartaric and oxalic acids and was neutralized with dil. ammonium hydroxide (litmus), brought to boiling, then treated with a 10% solution of calcium chloride and allowed to stand overnight. The precipitate, which had separated was collected, dried and weighed; yield, 28.3 g. This was extracted with a 20% solution of sodium hydroxide, the extract neutralized with hydrochloric acid (litmus) and allowed to stand overnight. The calcium mesotartrate was then collected, dried and weighed; yield, 24.5 g. or 48.7% of mesotartaric acid.

Anal. Subs., 0.4603, 0.4456. CaO, 0.1087, 0.1048. Calcd. for $C_4H_4O_6Ca \cdot 3H_2O$: Ca, 16.53. Found: 16.87, 16.79.

Determination of water. Subs., 0.5889. H_2O , 0.1301. Calcd. for $C_4H_4O_6Ca \cdot 3H_2O$: H_2O , 22.30. Found: 22.09.

Titration of the free acid with sodium hydroxide. Subs., 0.3306, 0.3353; required 38.25, 38.76 cc. of 0.1037 *N* NaOH (phenolphthalein). Calcd. for $C_4H_4O_6 \cdot H_2O$: 37.95, 38.49 cc.

The residual salt from the sodium hydroxide extraction was reprecipitated once, dried and analyzed.

Anal. Subs., 0.5929. CaO, 0.2275. Calcd. for $C_4O_6Ca \cdot H_2O$: Ca, 47.41. Found: 47.42.

Oxidation of Pyromucic Acid with Sodium Chlorate and Osmium Tetroxide

Five g. of pyromucic acid, 5 g. of sodium chlorate, 2 cc. of osmium tetroxide solution, and 25 cc. of water were brought together in a 250cc. Erlenmeyer flask fitted with a reflux condenser. The mixture was heated at 50° in a thermostat for 60 hours. The experiment yielded 4 g. of calcium mesotartrate and 0.5 g. of calcium oxalate.

In conclusion, I wish to express my sincere thanks to Professors H. S. Taylor and L. W. Jones for their invaluable suggestions in this research.

Summary

1. Vanadium pentoxide induces the oxidation of furfural and pyromucic acid with chlorates to give fumaric acid as the principal product.
 2. Osmium tetroxide also induces the oxidation of furfural and pyromucic acid with chlorates to give mesotartaric acid as the principal product and oxalic acid as the by-product.
 3. The mechanism of the reaction has been worked out and malic acid aldehyde has been isolated as the intermediate product.
 4. An acid having the empirical formula $C_5H_4O_6$ has also been isolated.

RESEARCHES ON SELENIUM ORGANIC COMPOUNDS.

VII. THE SYNTHESIS OF 2-PHENYL-, 2-FURYL- AND 2-THIENYL-BENZOSELENAZOLES, OF 2-PHENYL-BENZOSELENAZOLE-4'-ARSONIC ACID AND OF OTHER BENZOSELENAZOLES¹

BY MARSTON TAYLOR BOGERT AND ARTHUR STULL²

RECEIVED APRIL 1, 1927

PUBLISHED AUGUST 5, 1927

Nitro-, amino- and hydroxy-phenyl-benzoselenazoles have been synthesized by methods entirely analogous to those developed in these Laboratories for the corresponding benzothiazoles, by condensing the zinc *o*-aminoselenophenolate with the appropriate aldehyde or acid halide. As was expected, these compounds proved rather more difficult to prepare and less stable than their sulfur analogs.

Perhaps the most remarkable result of these syntheses is the persistence of the "Rosenkoerper" odor of 2-phenyl-benzothiazole even when the thiazole sulfur is replaced by selenium and the phenyl by a furyl or thienyl group. The odor of the dry compounds at ordinary temperature is faint, but when heated or in solution is of pronounced geranium or tea-rose type.

Further, these furyl (I) and thienyl (II) derivatives present new and

interesting combinations of dissimilar heterocyclic systems, which offer

¹ That portion of this paper which deals with the arsonic acid was presented at the Washington Meeting of the National Academy of Sciences, April 26, 1926. The other syntheses were reported to the Division of Organic Chemistry of the American Chemical Society, at the Philadelphia Meeting, September 8, 1926.

² Research Assistant, Columbia University, for the academic year 1925-1926.

opportunities of determining differences in the behavior of the cycles when attacked by various reagents.

Through the courtesy of Dr. Francis Carter Wood, Director of the Crocker Institute of Cancer Research, the sodium salt of the arsonic acid was tested, by intravenous injection, on mice and rats. It proved to be quite toxic to the host and without curative action on tumor growths in these animals. For healthy mice weighing 14–18 g. the lethal dose was 0.00025 g. and for rats of 40–50 g. the maximum tolerated dose was 0.00075 g. Its action upon various pathogenic microorganisms also will be investigated.

Experimental Part

***o*-Nitrophenyl Diselenide, $(\text{O}_2\text{NC}_6\text{H}_4)_2\text{Se}_2$.**—The method of Bogert and Andersen³ was varied in several particulars, and the following process was found to give the best results.

A mixture of 25 g. of sodium selenide in 250–300 cc. of 95% alcohol was refluxed until a clear solution was obtained, when 16 g. of finely pulverized metallic selenium⁴ was added and the refluxing continued for half an hour longer. This dark reddish-brown solution was gradually stirred into a warm solution of 50 g. of commercial *o*-nitrochlorobenzene in 100 cc. of alcohol and the mixture was refluxed for two to three hours additional. The use of a slight excess of sodium diselenide was found advantageous. As the hot solution cooled, the nitrophenyl diselenide separated. It was removed, washed thoroughly with water and with alcohol, and then formed a greenish-brown microcrystalline solid; yield, 37 g., or 57%. Recrystallized from glacial acetic acid to the constant melting point of 209° (corr.), it appeared as a pale brownish microcrystalline solid, readily soluble in benzene. Bogert and Andersen reported a melting point of 206.2–206.5° (corr.) for their product; Bauer,⁵ who prepared it by a different method, found 209°.

***o*-Aminoselenophenol, $\text{H}_2\text{NC}_6\text{H}_4\text{SeH}$.**—From the nitrophenyl diselenide, the zinc salt of the aminoselenophenol was obtained by the method of Bogert and Andersen.³ When a carefully purified nitro diselenide was used, the yield of zinc salt was 81%; with a crude diselenide, 55%. The product in the latter case also was found suitable for further syntheses.

As it separates first, the pure zinc salt is practically colorless, but it rapidly turns yellow and then brown in the light. Our observation in this matter is therefore at variance with that of Bauer,⁵ who prepared the salt in another way and reported that it was stable in the air.

2-Phenyl-benzoselenazole, $\text{C}_6\text{H}_4 \begin{array}{c} \text{Se} \\ \diagup \quad \diagdown \\ \text{N} \end{array} \text{CC}_6\text{H}_5$, was synthesized from

the zinc salt of *o*-aminoselenophenol and benzoyl chloride, as described by

³ Bogert and Andersen, *Proc. Nat. Acad. Sci.*, 11, 217 (1925).

⁴ The selenium used in this investigation was supplied by the Baltimore Copper Smelting and Rolling Co., through the courtesy of E. W. Rouse, Jr., General Superintendent, for whose assistance we are most grateful.—M. T. B.

2-(*p*-Nitrophenyl)-benzoselenazole, C₆H₄CC₆H₄NO₂(*p*).—An intimate mix-

ture of finely pulverized zinc *o*-aminoselenophenolate (1 mole) and *p*-nitrobenzoyl chloride (2 moles) was fused for an hour at 100°. The reaction began at about the melting point of the chloride (71–73°). The cooled melt was pulverized, washed with water to remove zinc salts and with sodium carbonate to eliminate any *p*-nitrobenzoyl chloride or *p*-nitrobenzoic acid. Sodium hydroxide solution is not suitable, since it dissolves some of the selenazole also. The crude yellow product was decolorized and crystallized from glacial acetic acid until the melting point remained constant at 211° (corr.). The crystals, when finally washed with a little alcohol and dried at 100°, appeared in minute, pale yellow, lustrous, short needles.

2-(*m*-Nitrophenyl)-benzoselenazole was prepared in the same way as the *p*-nitro isomer, and the reaction began as soon as the *m*-nitrobenzoyl chloride melted (about 35°). The crude product was crystallized from glacial acetic acid by adding three volumes of water to the hot solution, and was then recrystallized from 95% alcohol until the melting point remained constant at 148° (corr.). Further crystallizations from glacial acetic acid, ethyl acetate, acetone or benzene failed to change this melting point. In appearance, the pure compound resembled its *p*-nitro isomer, except that it was much paler in color.

2-(*o*-Nitrophenyl)-benzoselenazole.—Attempts to get this isomer pure have proved futile so far, but a crude product was obtained which yielded the pure *o*-aminophenyl-benzoselenazole upon reduction.

When zinc *o*-aminoselenophenolate and *o*-nitrobenzoyl chloride were brought together, even at temperatures near 0°, an explosion occurred with separation of carbon and zinc oxide. This is entirely similar to the experience of Smidth⁷ on bringing together the same chloride with the zinc *o*-aminothiophenolate.

When the zinc salt and nitrobenzoyl chloride were allowed to interact in glacial acetic acid solution, a yellow, gummy product separated which, after washing with water and with sodium carbonate, still contained zinc in apparent chemical combination. All attempts to isolate from this any pure compounds failed. It was therefore reduced

⁵ Fromm and Martin, *Ann.*, **401**, 178 (1913). Bogert and Chen, *THIS JOURNAL*, **44**, 2355 (1922).

⁷ Smidth, *Dissertation*, Columbia University, 1925, p. 31.

directly, by tin and dil. hydrochloric acid, to the 2-(*o*-aminophenyl)-benzoselenazole, in much the same way as described for the following *m*- and *p*-amino isomers. Recrystallized from 75% alcohol to the constant melting point of 142.5° (corr.), it formed minute, pale greenish-yellow, lustrous scales, whose alcoholic solution exhibited no fluorescence; yield, 1.5 g. from 4 g. of the crude initial material.

2-(*m*-Aminophenyl)-benzoselenazole.—A mixture of 2 g. of the corresponding nitro derivative, 10 cc. of concd. hydrochloric acid, 90 cc. of water and 10 g. of granulated tin was boiled for three hours. Complete solution of the nitro derivative ensued within less than two hours. The hot filtrate from the excess of tin was stirred gradually into an excess of 4*N* sodium hydroxide solution, which precipitated the amine. After this alkali mixture had been kept warm for several hours, it was cooled and filtered. The crude amine was decolorized and crystallized from 50% alcohol, when it appeared in pale yellow, glassy needles, which dissolved in alcohol without fluorescence.

2-(*p*-Aminophenyl)-benzoselenazole was prepared in the same way as the *m*-amino isomer, and resembled it closely, except that the crystals were paler in color and their alcoholic solution exhibited a light violet fluorescence.

2-(*o*-Hydroxyphenyl)-benzoselenazole.—When a mixture of 1 g. of zinc *o*-aminoselenophenolate, 1 g. (an excess) of salicyl aldehyde and 125 cc. of glacial acetic acid was boiled for an hour, a clear, dark brown solution resulted. When left overnight at laboratory temperature, this solution deposited a small amount of zinc acetate and some metallic selenium. The filtrate from this deposit was diluted with three volumes of water, the curdy, brown precipitate separated and crystallized repeatedly from 50% alcohol; yield (after first crystallization from alcohol), 23%. The pure product formed fine, transparent needles of pale yellowish tinge, soluble in sodium hydroxide but not in sodium carbonate solution, and which gave no color reaction with ferric chloride either in aqueous or in alcoholic solution.

2-(*p*-Hydroxyphenyl)-benzoselenazole, produced similarly from the *p*-hydroxybenzaldehyde, using 0.6 g. of the aldehyde per gram of the zinc salt, formed larger and practically colorless, glassy needles, but in other respects resembled its *o*-isomer; yield, after one crystallization from alcohol, 46%.

The cooled and pulverized product was warmed with an excess of *N* sodium hydroxide solution, and the insoluble material was heated in a porcelain dish. A sublimate was obtained which crystallized from toluene in colorless, glistening scales, m. p. 314° (uncorr.), which gradually turned brownish on standing in the light and air.

Anal. Calcd. for $\text{C}_{14}\text{H}_8\text{N}_2\text{Se}_2$: Se, 43.70. Found: Se, 43.74.

a suspension of 1 g. of 2-(*p*-aminophenyl)-benzoselenazole in 20 cc. of 2 *N* hydrochloric acid and 30 cc. of water, cooled to 0°, there was added slowly 0.5 g. of sodium nitrite dissolved in 10 cc. of water. The resulting solution, containing some suspended diazonium salt, was added to an ice-cold solution prepared from 5 g. of potassium arsenite, 50 cc. of water, 12 cc. of *N* sodium carbonate solution and 1 to 2 g. of copper bronze powder. The mixture was shaken from time to time, and tested periodically with litmus to make sure of its alkalinity. After standing for an hour at room temperature, it was heated at 100° until all frothing ceased (1 to 2 hours). During this heating, a slight odor was noted resembling that of 2-phenyl-benzoselenazole.

The alkaline mixture was filtered warm and the insoluble material was washed with a little warm sodium carbonate solution. The combined greenish filtrate and washings were acidified with concd. hydrochloric acid, the pale yellow, flocculent precipitate was removed, washed thoroughly with water and dried at 100°. Recrystallized from 50% alcohol, it formed microscopic, pale yellow scales, which melted with decomposition above 360°; yield, 27%. It dissolved readily in alcohol, but slightly in water, chloroform or acetone, and was practically insoluble in ethyl acetate or carbon disulfide. In alkali hydroxide or carbonate solution, it was easily soluble and was reprecipitated when these solutions were acidified.

Anal. Calcd. for $C_{12}H_{10}O_2NAsSe$: C, 40.82; H, 2.61; Se, 20.72; As, 19.61. Found: C, 42.62; H, 3.05; Se, 20.41; As, 17.80.

As these figures demonstrate, the analysis was a troublesome one, because of the particular elements present and the small amount of product isolated. Arsenic was determined as follows.

The substance was digested in a Kjeldahl flask with a small amount of concd. sulfuric acid and with additions of concd. nitric acid from time to time, to assist in the oxidation of the arsenic to arsenate. When the oxidation was complete, the colorless solution was diluted, made slightly ammoniacal, magnesia mixture added, then the whole was made strongly ammoniacal and left overnight. The precipitated magnesium arsenate was washed, dried and converted into pyro-arsenate.

A blank run in exactly the same way with 2-phenyl-benzoselenazole showed that no selenium was thrown down by magnesia mixture.

MONOSODIUM SALT—When the free arsonic acid and the calculated amount of 10% sodium hydroxide solution were brought together in absolute alcohol solution, the monosodium salt separated immediately as a fine, white solid, which was removed, washed thoroughly with absolute alcohol and dried; yield, practically that calculated. It is believed to be the first water-soluble organic selenium arsenic compound ever prepared.

2-(α -Furyl)-benzoselenazole (Formula I).—A mixture of one mole of zinc *o*-aminoselenophenolate with two moles of pyromucyl chloride was heated at 100° for 30 minutes, the cooled and pulverized melt extracted with *N* sodium hydroxide solution, to remove excess of acid chloride, and the residue decolorized and crystallized from 50% alcohol until the melting point remained constant at 133° (corr.). The compound formed colorless, glistening scales, with the characteristic agreeable odor of 2-phenyl-benzothiazole ("Rosenkoerper"); yield, 83%.

Anal. Calcd. for $C_{11}H_7ONSe$: C, 53.18; H, 2.82; Se, 31.90. Found: C, 54.20; H, 2.97; Se, 31.51.

2-(α -Thienyl)-benzoselenazole (Formula II), was prepared from the zinc *o*-aminoselenophenolate and α -thienyl chloride in much the same way as the α -furyl derivative just described. Decolorized and crystallized from 95% alcohol to the constant melting point of 114.5°, it was obtained in well-formed, glassy, lustrous prisms, of a pale greenish-yellow color, and with the same odor as the α -furyl derivative; yield, 60%. From 50% alcohol, it crystallized in smaller, practically colorless needles, of the same melting point. It is believed that this is the only organic compound known which contains both unoxidized sulfur and unoxidized selenium in its molecule and yet has an agreeable odor.

Anal. Calcd. for $C_{11}H_7NSe$: C, 49.99; H, 2.64; Se, 29.97. Found: C, 51.64; H, 2.86; Se, 30.15.

Analysis of Benzoselenazoles

So much difficulty was encountered in getting satisfactory carbon determinations in the combustion of these selenazoles, that in the case of many of the new products selenium was determined instead.

Bauer⁸ tested the methods of Frerichs,⁹ Becker and Meyer¹⁰ and Michaelis,¹¹ and found the latter the most satisfactory. It has the disadvantage, however, of requiring the use of sealed tubes.

We found that the following process gave very good results.

The sample (0.2–0.3 g.) was heated carefully in a small Kjeldahl flask with the minimum amount (8–10 cc.) of concd. sulfuric acid until a clear, colorless solution was obtained (4–7 hours). The cold acid solution was rinsed into a beaker, diluted to about 200 cc. and neutralized with concd. ammonium hydroxide solution. An excess (50–60 cc.) of concd. hydrochloric acid was added, the solution heated to boiling and saturated with sulfur dioxide. The selenium separated at first in the red, colloidal form but soon turned gray and precipitated. After standing overnight, the selenium was filtered out on a Gooch crucible, washed with water until free from chloride ion, then with a little alcohol, dried at 105°, and weighed as metallic selenium.

Summary

1. Zinc *o*-aminoselenophenolate yields the corresponding 2-nitro- or 2-hydroxyphenyl-benzoselenazoles when condensed with the proper nitro- or hydroxybenzaldehydes; with oxalyl chloride it gives the *bis*-benzoselenazolyl, and with pyromucyl and α -thienyl chlorides the α -furyl- and α -thienyl-benzoselenazoles, both of the latter possessing very agreeable odors.

2. From the nitro derivatives, the corresponding amines were obtained by reduction, and an arsonic acid from the 2-(*p*-aminophenyl) derivative by means of the Bart reaction.

3. The sodium salt of the arsonic acid was found to be without curative value when tested upon mouse tumors.

EFFECT OF POLARIZED LIGHT ON THE PHARMACOLOGICAL PROPERTIES OF SOME DRUGS¹

BY DAVID I. MACHT AND W. T. ANDERSON, JR.

RECEIVED APRIL 18, 1927

PUBLISHED AUGUST 5, 1927

Introduction

While the effect of light on chemical reactions has been known for a long time, and photochemistry has been receiving adequate attention for many years, the influence of light and other radiations on the pharmacological properties of drugs has not been studied until comparatively the last few years.

In the last decade or two, attention has been directed to the important role played by ultraviolet rays on the toxicity of a number of dyes, and very much more recently the effect of such radiations has come into prominence in connection with the marvelous strides in our knowledge of the vitamins. The earlier work on the dyes is summarized by Tappeiner and Jodelbauer² who have reviewed the previous work on the subject and contributed some original observations. These authors have found that eosin, while relatively non-toxic for paramecia in the dark, is very destructive to the same animalcules when irradiated by ultraviolet rays. Straub³ analyzed this photo-dynamic effect further and obtained some evidence pertaining to oxygen being activated in the course of this phenomenon. Noguchi⁴ and others have studied effects of light on the bactericidal properties of some dyes. Amsler and Pick⁵ and Kolm and Pick,⁶ studying the effects of eosin solutions on isolated organs, found that that compound was much more active when irradiated by ultraviolet rays than in the dark. Macht and Teagarden⁷ studied the effect of ultraviolet irradiations on the fluorescent solutions of quinine and quinidine sulfates and found that these solutions were more active when so irradiated. Recently Macht⁸ noted that the toxicity of sodium benzoate for yeast is much greater when exposed to sunlight than in the dark, and the remarkable experiments of Hess

¹ Read before a joint session of the Organic and Biological Divisions of the American Chemical Society at the Richmond meeting, April 12, 1927. A preliminary note on part of the subject was published by David I. Macht and J. C. Krantz, Jr. [*J. Am. Pharm. Assoc.*, 16, 106 (1927)].

light the black diamond-shaped slit was substituted for the prism as described above.

Inasmuch as the authors have found, as will be shown further on, that irradiation, even with weak light, when polarized produces definite changes in drugs, another and slightly modified type of apparatus was employed in a different series of experiments. This set-up or arrangement was used in some of the most carefully and accurately performed experiments carried out by the authors, and consisted of the following. A wooden box with a detachable top is blackened inside and outside. Inside the box at one end is an attachment in which is fixed a rectangular quartz cell for the solutions of drugs. At the other end of the black box directly opposite the quartz cell is a circular aperture into which can be fitted snugly a Nicol prism, 2.5 cm. in diameter and 6 cm. long. In obtaining polarized light, the tube containing the Nicol prism is placed in the aperture so that its long axis is parallel to the table. In front of the Nicol prism is placed a small Spencer microscope lamp provided with a daylight filter. This lamp consists of a small Mazda lamp of 15 watts, enclosed in a dark cell with a window of glass which allows the light to diffuse through. The light from this lamp passing through the Nicol prism is polarized so that the drug contained in the quartz cell inside the black box is irradiated with polarized light. The amount of such polarized light and its intensity were very carefully determined by means of a thermopile. The exact wave lengths of which the light consisted were also determined by the spectrograph. In order to obtain a control light of exactly the same intensity and quality, with the exception of its not being polarized, the lamp is moved to a position from the aperture of the black box and the Nicol prism is removed. With the lamp in this position, and the Nicol prism taken out, the light entering the box is so calibrated as to be the exact control of the polarized light which was used. By means of this apparatus, which we may call for brevity the M.-A. (Macht-Anderson) apparatus, a drug can be radiated with polarized and non-polarized light for any given length of time so as to have the two forms of light of exactly the same intensity and wave length. Examples of experiments performed with the above apparatus will be given in the following section.

In order to obtain polarized light by the method of glass plates a different kind of apparatus was constructed. This apparatus was designed carefully by one of the authors and Professor A. H. Pfund, of the Department of Physics, Johns Hopkins University, and was constructed under Professor Pfund's supervision and calibrated by him. The plan of this apparatus is as follows. A box or cell in the form of a truncated pyramid 80 cm. high was constructed with a lower base 60×45 cm. and upper end about 25 cm. square, the back of the wall of the cell being perpendicular to the base, and the front wall and door slanting. At the upper

or small end of the cell a socket is fixed, into which is inserted a large, round, Mazda tungsten nitrogen electric bulb, of 500 watts power, which serves as source of light. The lower part of the apparatus or cell is divided into two compartments, completely separated from each other by a blackened partition. The light of the Mazda lamp is allowed to penetrate into the chamber on one side of the apparatus after first passing through a dozen plates of smooth glass, placed at the "polarizing" angle, so that this chamber is illuminated with highly polarized light. The light from the same Mazda lamp, on the other hand, is allowed to penetrate into the second or neighboring chamber after first passing through a pile of smooth plates of glass placed perpendicular to the line of propagation of the light, so that this second chamber is illuminated with non-polarized light. The number of glass plates in this second pile was adjusted so that the intensity of the non-polarized light was just equal to the intensity of the polarized light in the first chamber. By boring apertures in the floors of the two respective chambers and taking spectrophotographs of the two transmitted lights, it was found that the spectral range of light waves in the polarizing and non-polarizing chambers was the same, the shortest waves transmitted being about 3650 Å. The temperatures in the two chambers were practically the same, not deviating from each other by more than a fraction of a degree.

The source of light was an electric bulb of 700 candle power. This intensity, of course, was cut down by passage through the piles of plates, but the intensity of the transmitted light in each chamber was made the same by photometric calibration in the Physics Laboratory, performed by Professor A. H. Pfund. The intensities in the two chambers were compared by Professor Pfund by reflecting the lights passing through the two sets of glass plates, from a white surface, and allowing the rays to pass through a Lummer tube. The light from the two chambers was thus reflected diffusely, and hence was depolarized before the comparison was made. Thus, while the eye was used in comparing, it could not be argued that there might be a difference in the physiological effects of polarized and non-polarized lights on the eye. Of course such an objection would be purely hypothetical as, so far as is known, no difference in the effects on the eye between polarized and non-polarized lights has ever been noted, and if such a difference should be experimentally demonstrated, it would be a fundamental physiological discovery.

In order to make sure that small variations in intensity of the control did not affect the results, a number of experiments were made with the non-polarized light of a slightly greater or slightly lesser intensity than the polarized light (by changing the number of plates in the control chamber). Such variations did not appreciably change the marked effect of the polarized light.

The temperatures in the two chambers were the same to within a fraction of a degree, as indicated by thermometer readings and also by thermographic tracings. Here again a number of experiments were made in which the temperature in the control chamber was purposely made a little higher or a little lower than in the polarizing chamber, respectively, and the results obtained still showed a marked difference between the effects produced by polarized and non-polarized light.¹²

Methods of Pharmacological Evaluation

The drugs studied intensively in the present paper were a galenical preparation of tincture of digitalis and the pure crystalline drug cocaine, either in the form of the free base or of the hydrochloride. The hydrochloride of cocaine was used in most cases because of the very poor solubility of the alkaloid itself. In addition to these two drugs, the authors have studied also a number of others and more particularly quinine and cinchonidine. Extensive work is in progress on several important alkaloidal and other drugs, which will be reported in a later paper.

It is a well-known fact that physiological test objects are often so sensitive to the pharmacological effects of certain chemicals or drugs that by their means one can detect changes in those drugs much more easily than by any quantitative chemical methods. Indeed it is a fact that some of the most potent and important medicinal substances employed by pharmacologists and physicians can be standardized or assayed only by biological methods. Thus, for instance, the uterus of the virgin guinea pig will respond to such dilute concentrations of histamine as could not be quantitatively estimated by even the more refined microchemical methods and the very highly potent chemical body "A" obtained by Professor Abel¹³ from the posterior lobe of the pituitary gland, is some 40 or even more times more powerful in this respect, as shown by tests on the isolated uterus and on certain preparations of the urinary bladder.¹⁴

Digitalis, undoubtedly one of the most important and useful drugs in the Pharmacopeia, is a drug the chemistry of which is still but incompletely known, and the only methods by which the therapeutic efficiency or potency of digitalis preparations can be estimated and compared are biological. While cocaine is a well-known chemical entity and its chemical structure is very well understood, a dilute solution of it can be assayed chemically only with the greatest difficulty or almost not at all, and even then the results are not sufficient for determining its pharmacological activity. The same is true of the majority of alkaloidal drugs employed by pharmacologists and physicians, so that in order to evaluate various samples of

¹⁴ Macht, *J. Pharmacol.*, 27, 389 (1926).

the same drug biological or pharmacological methods of assay are quite indispensable and indeed are absolutely essential.

In the present work where the purpose of the irradiations was to detect even the smallest changes in the pharmacological properties of certain drugs, chemical methods could be employed only to a limited extent; the greatest amount of information had to be obtained and the greater reliance placed on pharmacodynamic tests and analyses.

Tincture of digitalis was used almost exclusively in the study of digitalis. The methods of assay employed in this case were of different kinds. In the first place the standard cat method of Hatcher and Brody was employed,¹⁵ the exact technique being a slight modification introduced by Rowntree and Macht.¹⁶ This method consists in the regular injection of tincture of digitalis diluted 1:10 with physiological saline solution into the femoral vein of a cat under light ether anesthesia. The injections are continued as described by the authors until the arrest of the heart in systole. An average of three experiments is usually made for an assay. The cat method has recently been shown by Lind Van Wijngarden, on the basis of a very large number of animal experiments, to yield quite reliable results in experienced hands.¹⁷ The figures from which averages were made lay well within the experimental variation allowed by the formula of Wijngarden, that is, the mean of the percentage deviations from the average value of the N estimations made was less than $6.67 \sqrt{N-1}$.

A still more sensitive and reliable method, especially for comparative examinations of different samples, has been described by one of the authors in collaboration with Krantz.¹⁸ In contradistinction to the cat method which is a zoöpharmacological method, this method is phytopharmacological, employing living seedlings or plants as the biological test objects. These two methods, the cat method and the plant method, were used almost exclusively by the authors in the study of tincture of digitalis. In addition to these a comparison of digitalis tinctures exposed to polarized and non-polarized light was also made by other methods. Thus, in some cases, the goldfish method of Pittenger and Vanderkleed was used.¹⁹ In still other experiments the comparative potency of the specimens treated with different forms of light was tested on frogs' hearts and finally some comparative tests were made by very interesting and effective methods described by Hanzlik and Shoemaker, in which the emetic effect of digitalis on pigeons is used as a criterion.²⁰ It may be stated at once that the results obtained by *all* of the above methods of experimenta-

tion with digitalis were quite concordant and in most cases at least two methods, namely, the cat and the plant methods, were used in examining each sample, so the results were doubly reliable.

The evaluation of cocaine in weak solutions, such as are generally employed in surgical practice and which are known to be easily decomposed by heat and other physical agents, is very difficult by chemical means, and moreover gives little information as to the therapeutic or pharmacological efficiency of the drug. In order to detect deterioration in cocaine solutions more effectively, two new and very delicate methods have been elaborated by one of the authors, one of these being a zoöpharmacological method and the other being phytopharmacological. In the *zoöpharmacological* method the effect of cocaine solutions was studied on goldfish, *Carassus aureus*. It was found that when fish are placed in even very dilute solutions of cocaine hydrochloride, for instance 1:10,000, they gradually become anesthetized and lose their sense of equilibrium. The fish "keel" over and finally float on their sides. A longer exposure leads to paralysis and death. To compare two specimens of cocaine, solutions are diluted to the same concentration in two vessels, small goldfish are immersed in the same and their behavior is studied. There is usually a preliminary stage of excitement which is followed by an anesthetic and a paralytic stage, and by noting the rapidity of onset of these phenomena it is easy to determine which solution is the more active pharmacologically. The more active solution in these cases is the one which produces anesthesia and paralysis more quickly.

The *phytopharmacological* method employed is even more delicate than the goldfish method. This method is based on the remarkable observations of Macht and Livingston obtained in a comparative study of the effects of cocaine on animal and plant protoplasm.²¹ It was found by those authors that whereas the cocaine molecule itself is not very toxic for living seedlings of *Lupinus albus*, requiring sometimes as much as 6% or more of the solution of cocaine hydrochloride to inhibit growth completely, and not affecting growth at all in concentrations of 0.17%, the decomposition products of the cocaine molecule behaved very differently. When the cocaine molecule is hydrolyzed or broken down it yields one molecule each of the base ecgonine, methyl alcohol and benzoic acid according to the following equation:

Of these decomposition products benzoic acid, when tested on animal preparations (in the form of sodium benzoate) is practically non-toxic, but when tested on plant preparations sodium benzoate is extremely toxic. It was found that as little as 0.0007 of 1% inhibited growth of *Lupinus*

²¹ Macht and Livingston, *J. General Physiol.*, 4, 573 (1922).

albus completely, and 0.004% produced an appreciable inhibition of growth of the roots. This method suggested a delicate means of determining the decomposition of cocaine solutions. The greater the decomposition, the greater the toxicity of the solutions becomes for the growth of living seedlings. In the present investigation this method yielded very striking results, as will be seen from Table I. In most of the experiments solutions of cocaine hydrochloride were used, but in some weak solutions of the alkaloid cocaine itself were also studied. Slight changes in the hydrogen-ion concentration of the solutions were found to produce no appreciable effect on the growth of the seedlings, so that the inhibition of growth was due actually to the decomposition products and more particularly to benzoic acid.

In addition to the above zoöpharmacological and phytopharmacological methods of evaluating cocaine solutions, samples of cocaine hydrochloride which were exposed to polarized and non-polarized light were also tested in other ways. The comparative *anesthetic* effect of the two solutions was studied on the cornea of the rabbit. The comparative anesthetic effect was also studied on the living frog skin. Finally, the anesthetic effect on human beings was studied on some subjects by direct application to the mucous membrane of the cheeks. The difference between solutions of cocaine exposed to polarized and non-polarized light was also tested by physical chemical methods, namely, the determination of their hydrogen-ion concentration. We are indebted to Mr. W. C. Harden for his kind assistance in this work.

In evaluating the potency of quinine and cinchonidine sulfates and other salts, the authors again made use of the phytopharmacological method. Several years ago one of the authors described the effect of solutions of cinchona alkaloids on the growth of plants and found that they were quite toxic for them.²² A comparative study of the toxicity of solutions of such alkaloids, therefore, was made by noting the growth of seedlings of *Lupinus albus* in definite percentage solutions of the drugs studied.

A few determinations were made also of the optical activity of quinine. In this case a quinine tartrate solution was employed which has been shown by Martinotti to be useful in the study of the keeping qualities of the drug, by means of observations on its optical rotation.²³

Experiments with Digitalis

Irradiation of digitalis tincture was performed by all of the methods described above. Tinctures of digitalis were taken and in each case a given specimen was divided into two parts. One of these was irradiated with

²² Macht, *Proc. Soc. Exptl. Biol. Med.*, 20, 1971 (1922).

²³ Martinotti and Martinotti, *Notiz. chim. ind.*, 1, 182 (1926).

polarized light; the other was irradiated with non-polarized light of the same intensity as a control. Occasionally the control with non-polarized light was irradiated with a stronger intensity of light or for a longer period of time. In all experiments the authors found that irradiation with polarized light produced a *change in the potency* of the tincture. Table I gives ample illustration of the findings.

In Expt. 101 irradiation was through a Nicol prism for one hour. The tincture of digitalis was in a glass test-tube, and the source of light was a Krohmayer lamp. In Expt. 106 irradiation was performed by the Macht-Pfund apparatus. The assay of the digitalis in these two experiments is given by the phytopharmacological method. Expts. 10 and 16 give the results obtained with irradiation by means of the Nicol prism and the Macht-Pfund apparatus, respectively, as indicated by assay experiments on cats. It will be noted that in each of these experiments irradiation with polarized light produced a deterioration of the tincture as indicated by a weaker pharmacological action of the same. It should be noted also that in all of these experiments the light employed consisted of rays belonging only to the visible spectrum plus some of the infra-red rays.

Expt. No. 200 was performed with the Macht-Anderson apparatus described above and in order to indicate the care exercised in controlling all the conditions in the experimentation, the physical data are here given in full. The apparatus used was the same as described above, the source of light being a microscope lamp with a daylight filter. The time of irradiation for each specimen, polarized and non-polarized, was exactly two hours. The radiation intensity for both polarized and non-polarized light was 70 ergs/sec./mm.² The light from the microscope lamp as determined by spectroscopic examination consisted of the visible rays and infra-red rays. All of the measurements were made with the greatest care by means of the thermopile. The average light intensity at the surface of the irradiated solution inside the blackened box was 5.538 ergs/sec./mm. the measurements in this case being made through water so that infra-red rays of more than 14,000 Å. were eliminated. The time of irradiation as stated above was two hours, or exactly 7200 seconds. The average light intensity measured here is the value obtained when the total intensity falling on the area is divided by area. This is necessitated by the fact that the light transmitted by the prism is not disposed uniformly. These very careful measurements established beyond a shadow of a doubt that any difference between the specimens obtained after irradiation must be due to polarization of the light because this was the only variable, the intensity, time of irradiation, the volume, surface and concentration of the drug irradiated being in all instances identical. It will be noted from the protocols of Expt. 200 that the assay of the polarized and non-polarized specimens by the cat method, by the plant method and by the pigeon

method all indicated that the polarized specimen was much more deteriorated than a non-polarized one.

Expt. 210 gives the results obtained by irradiation with the Krohmayer lamp. The tincture of digitalis here, as in previous experiments, was exposed in a quartz cell. In this case the rays transmitted were the visible rays with the exception of the extreme red and the ultraviolet rays ranging from 2500 to 4000 Å. In this experiment the polarized and non-polarized specimens were irradiated for 30 minutes each because the actual visible light intensity with this lamp was much higher than in the instance of the irradiation by the microscopic lamp. However, the intensity was lower because the microscope lamp produced an abundance of heat which was

not present from the light from the water-cooled Krohmayer lamp. The radiation density in this case, for both the polarized and non-polarized lights, was exactly the same, namely, 43 ergs/sec./mm.² The average light intensity at the surface of the irradiated source was in this case 42.66 ergs/sec./mm.² The intensity of this Krohmayer at the surface of the radiated specimen was 7.7 times that of the microscope lamp used above, while the time of irradiation with the Krohmayer was only one-fourth that used for the microscope lamp, or exactly 1800 seconds. Consequently, the samples irradiated by the Krohmayer rays received approximately twice as much light as those irradiated by the bulb. It was found that by irradiating digitalis tincture with ultraviolet light, a *further change or decomposition* in its constituents was produced. The tincture became actually more poisonous as indicated by the experiments on cats, pigeons and plants. Tincture of digitalis is a complex of a large number of active principles, the chemical nature of which is still not definitely known. It is, therefore, not at all surprising that progressive changes may be produced in it by irradiation with powerful rays for prolonged periods of time. The authors noticed in performing experiments on cats with such tinctures that the emetic properties of the tincture were markedly increased. This again indicated some change produced in the digitalis which is not ordinarily produced by the visible rays of light with which the other experiments were performed. *It is important to note, however, that here also it was the polarized light which produced a photodynamic effect, whereas the non-polarized control was relatively unaffected.*

Expts. 30 and 40 were performed with a Nicol prism and a Mazda nitrogen electric bulb of 75 watts.

Experiments with Cocaine

Table II exemplifies the effect of light on cocaine. In Expts. 120 and 50 the solutions were irradiated through a large Nicol prism. In Expts. 125 and 51 they were irradiated in the Macht-Pfund apparatus. It will be noted that in each case cocaine exposed to polarized light was markedly changed from the normal solution on the one hand and the one exposed to non-polarized light on the other hand. This was indicated by its lesser toxicity for animals (goldfish) and greater toxicity for seedlings, as explained above. Hydrogen-ion determinations also showed a change in the polarized specimens.

Expt. 220 shows the effect of polarized light of different wave lengths on solutions of cocaine hydrochloride. In this case irradiations with visible and infra-red rays were performed by the Macht-Anderson apparatus and microscope lamp under exactly the same physical conditions as described in the digitalis experiments. Irradiation with visible and ultraviolet rays was performed with the Krohmayer lamp with the same

physical constants as described under digitalis. Finally, ultraviolet rays alone were used in the third part of the experiment, by allowing the rays from the Krohmayer lamp to filter through a Corning filter G986A which allowed the rays from 2500-4000 Å. only to filter through. It will be noted in the case of cocaine that irradiations with polarized light of both short and long wave lengths produced a deterioration of the drug solution. This was tested out in every conceivable way; on living seedlings, on goldfish, on the rabbit's cornea, on the living frog's skin and on human mucosa.

^f The more cocaine decomposed, the less the toxicity for animals.

^g December 5, 1925, irradiated one hour with Nicol prism.

^h December 8, 1925, irradiated three hours in Macht-Pfund apparatus.

In all three cases, the non-polarized specimens were more toxic on fish, and more anesthetic on rabbit's cornea, frog's skin and human mucosa.

Experiments with Quinine and Cinchonidine

In experiments with quinine and cinchonidine, solutions of quinine and cinchonidine sulfates, respectively, were used in most of the experiments. In some of the experiments a solution of quinine tartrate was examined. Irradiation of these solutions with polarized and non-polarized light of the visible spectrum by means of either a Nicol prism or the Macht-Pfund apparatus showed that such solutions became less toxic. This was easy to demonstrate quantitatively by means of phytopharmacological experiments. Expts. 60 and 70 will serve to illustrate the findings. In the case of quinine tartrate a few determinations with a polariscope were made which are indicated in Table III. Further polariscopic examinations are in progress.

^c January 20, 1926. Quinine sulfate irradiated for two hours in Macht-Pfund apparatus, 1 100,000 soln.

Experiments with Circularly-Polarized Light

In all of the above experiments with polarized light, *plane*-polarized light was obtained. The question naturally arises, what may be the effect of circularly-polarized light on the pharmacological properties of the above drugs? Such an investigation is at present in progress. It may be well, however, to state the results of a few preliminary experiments on the subject. The authors obtained circularly-polarized light by the use of the Macht-Anderson apparatus together with certain quartz plates. It has been found by physicists that if a ray of light passes through a plate of crystal quartz which has been cut perpendicularly to the axis, it is divided into two rays moving with different velocities, the vibrations in each ray, however, instead of being rectilinear and at right angles to one another, like plane-polarized light, are circular and in opposite directions. The ray of light is said to be circularly polarized. Ordinary complex light passing through such a plate will be circularly polarized, but the net result will be little, if any, different from that of the ordinary rays which were already vibrating in all directions. If the ray of light which passes through the quartz plate be already plane-polarized, for example, by means of a Nicol prism, the two beams emitted by the quartz plate will be circularly

polarized. Experiments were, therefore, performed by taking a quartz plate cut perpendicular to the axis of the crystal and allowing the plane-polarized light obtained by passing light from a microscope lamp through the Nicol prism to pass through this plate. Control experiments for the same were made by allowing the plane-polarized light to pass through another quartz plate cut parallel to the axis of the crystal. Table IV will give an idea of the results obtained with tincture of digitalis. The experiments indicate that circularly-polarized light produced even greater deterioration of the tincture than did the plane-polarized light. Further work on the subject is to be carried on.

TABLE IV
TINCTURE DIGITALIS

Macht-Anderson apparatus; 2cm. Nicol; microscope lamp; visible and infra red rays; exposure, 2 hrs.

Irradiated by	Lethal dose for cats, cc./kg.	Effect on seedlings, index of growth, %	Effect of 0.15 cc. on pigeons, vomiting in
(Normal, non-radiated)	11.2	59	3 min.
Non-polarized light	11.4	63	3 min.
Plane-polarized light	13.1	68	4 min.
Circularly-polarized light	15.1	73	6 min.

The authors are also planning to study the effects of polarized and non-polarized monochromatic lights.

Discussion

The experiments described above make it evident that polarized light may produce a profound change in the pharmacological properties of certain drugs. Perhaps the most remarkable fact in this connection is that such changes *are produced by polarized light of the ordinary or visible spectrum*. This is not only of scientific interest but of practical importance, as may be concluded from the following considerations. Polarized light is not at all as rare or uncommon as might be supposed on first thought. Wherever light is reflected from smooth surfaces some polarization occurs. Again, whenever light passes through certain transparent media such as glass at certain angles a little polarization takes place. It is known to physicists and physical chemists that transparent sheets of cellulose polarize light to a certain extent. In other words, thin sheets of paper which are more or less transparent produce considerable polarization of light that passes through them. Bearing this in mind the authors performed the following experiment. A tincture of digitalis was divided into two parts and corked tightly in two flint glass bottles of exactly the same shape and quality. One of the bottles was wrapped in thin tissue paper such as is often used by drug manufacturers for wrapping various vials of medicaments. The two bottles were left standing in the sunlight for several weeks and then the tinctures were assayed carefully both by the

plant method and by the cat method. It was found that while the quantity of light, as determined by physical measurements, that passed through the paper into the wrapped specimen of digitalis was less than one-sixth the quantity of light which passed through the uncovered glass bottle, nevertheless, the deterioration of the digitalis specimen in the paper-covered specimen was actually *greater* than in the uncovered specimen. Thus the index of growth for plant seedlings of *Lupinus albus* given by the uncovered specimen was 66%, whereas the index given by the paper-covered specimen was 71%. The lethal dose for cats of the uncovered specimen, was 9.2 cc. per kg., whereas the lethal dose of the paper-covered specimen was 10.6 cc. per kg., a difference of nearly 15%. Bearing in mind that the amount of light to which the covered specimen was exposed was less than one-sixth that of the uncovered specimen, these findings are truly remarkable. Similar results were obtained by exposing specimens of digitalis in test-tubes wrapped in thin tissue paper to the light from a large electric bulb. As another example of the practical importance of polarized light we may quote from a recent article on some interesting studies concerning the follicular hormone of the ovary, by Jordan and Doisy,²⁴ in the Proceedings of the Society of Experimental Biology and Medicine, December, 1926. We read, "In an earlier publication Allen and Ellis call attention to the destruction of the hormone by ultraviolet light. Some data, which confirm and extend theirs, have been obtained, but our most striking observations are upon the effect of diffuse daylight from north windows upon the activity of the hormone." To the present authors these findings have undoubtedly a significance in relation to polarized light, as may be made clearer by another citation. We quote from the pioneer work of Baly and Semmens on the hydrolysis of starch,²⁵ "In this connection it is interesting to note that in the living leaf the starch synthesized during the day undergoes hydrolysis to sugars in the early evening when, as is well known, the light from the sky is polarized. The results obtained would seem to show that plane-polarized light exerts very definitely a selective photochemical effect compared with ordinary light." Again, on page 253, we read "These experiments have been repeated more than twenty times and similar results were obtained in all. In the early observations some hydrolysis was sometimes observed on the slide exposed to ordinary light, and this effect varied in a remarkable way. It was found, however, that this was due to stray light reflected from the bench top and from the legs of the microscope stand, and also from the glass slide, and hence partially polarized. When this stray light was excluded, the abnormal effect vanished and constant results were obtained."

In the opinion of the authors the above phenomena can be explained

²⁴ Jordan and Doisy, *Proc. Soc. Exptl. Biol. Med.*, **24**, 216 (1926).

²⁵ Baly and Semmens, *Proc. Roy. Soc.*, **97B**, 280 (1924).

satisfactorily on the basis of the photochemical and the photopharmacological effects of polarized light.

While the phenomena and experiments just described are rather unusual, on more careful reflection they do not seem to be as unexpected as one might be inclined to regard them. They are no more striking than the fact that solutions of organic chemicals possessing an asymmetric carbon atom have the power of turning the plane of polarized light to the right or to the left. If "for every action there is a reaction" we may look at this phenomenon from the other end and argue that if a given solution can turn the plane of polarized light to the right or to the left, then *vice versa* we may expect polarized light also to react on the solution, and tend to produce some rearrangement of its molecules. This is, however, only by way of speculation. The authors may state in this place that they are continuing further work on the effects of polarized light on a considerable number of other drugs and have already sufficient evidence to indicate that many such drugs are changed in their pharmacological properties by such light. Furthermore, it may be stated in this place, it was interesting to find that wherever such a change in the pharmacological properties was produced by polarized light, an inquiry into the chemical structure of the drugs studied, so far as is known, revealed that they were optically active. These results which are not final but require further study make it evident that optical activity of various chemical compounds is of even greater importance than has hitherto been supposed. We may conclude with a quotation from an article by the late Professor Arthur R. Cushny on the biological relations of optically isomeric substances, "This optical activity is, in fact, the most persistent evidence of life which we possess. An optically active alkaloid or acid may be kept for centuries after the plant which formed it and the chemist who isolated it are dead, but it will still possess its optical activity, testifying that it was formed by some living thing either directly or indirectly. When we find an optically active substance in the earth, we may know at once that it arose through the agency of life. The petroleum we burn, for example, must have arisen from living tissues, for it is optically active. Not only is it the most persistent sign of life, but it is the most definite physical characteristic of life. No other can be measured in actual numbers in the same way."

Summary

1. The effect of polarized light of different wave lengths was studied on a number of drugs and more particularly on tincture of digitalis solutions of cocaine and its salts, and quinine.
2. Polarized light was obtained by the two classical methods: (A) with a Nicol prism, (B) by means of piles of glass plates.
3. Controls were carefully performed with non-polarized light of exactly

the same physical properties and with the same physical constants except as to polarization.

4. It was found that polarized light beyond any doubt produced a very definite change in the pharmacological properties of the drugs studied as compared both with the normal specimens and with specimens irradiated by non-polarized light.

5. The practical significance of the above observations is discussed.

THE SHIFT IN A NEAR INFRA-RED ABSORPTION BAND OF SOME BENZENE DERIVATIVES

BY JAMES BARNES AND W. H. FULWEILER

RECEIVED APRIL 27, 1927

PUBLISHED AUGUST 5, 1927

In connection with a search for possible spectroscopic methods of identifying hydrocarbons some work was done on the absorption spectra of the aromatic series. Aside from the practical aspects of the results obtained it was thought that a preliminary report of some of the data might be of theoretical interest to those who are working in this field.

The extensive investigations of Coblenz¹ and Puccianti² on infra-red absorption spectra of organic liquids gave many important results. In recent years, certain special fields have been studied in a more detailed manner. We refer to the works of Márton,³ Ellis⁴ and others who showed that there appeared in the absorption spectra of the carbon-hydrogen compounds which they investigated a series of bands all at approximately the same wave length and that the values of these wave lengths almost formed an harmonic series, the fundamental being near 6.5μ .

Apparatus and Methods

All the above-mentioned observers used a prism spectroscope with a radiometer or a thermopile as the detecting instrument. In our work on the absorption spectra of some hydrocarbons and petroleum oils we have been using a grating spectroscope and photographing the bands on plates sensitized with neocyanine.

The source of radiation was a 65-watt lamp with a short, straight filament. It was surrounded by a hood with a hole in its side. The light passing through this hole fell on a lens which rendered it approximately parallel. It then passed through the absorption cell to another lens which

¹ Coblenz, *Carnegie Inst. Pub.*, 1905-8.

² Puccianti, *Nuovo Cim.*, 11, 241 (1900).

³ Márton, *Z. physik. Chem.*, 117, 97 (1925).

⁴ Ellis, *Phys. Rev.*, 27, 298 (1926).

focused the light on the slit of the spectroscope. By means of screens with circular openings placed before and after the cell, only the light passing through the cell fell on the slit. The absorption cells were made from glass tubing 2 cm. in diameter with plane glass windows glued to ground ends and with side tubes for filling. Two lengths of cells were used, 18 and 30 cm., respectively.

A Rowland plane reflection grating was placed on the table of the spectrometer and carefully adjusted. The collimator and camera objectives had apertures of 3.5 cm. and their focal length was approximately 40 cm. Photographs were only taken in the first order spectrum and all lines of the second order which would affect the plates in the region under investigation were absorbed by a thin sheet of red glass placed in front of the slit. The photographs were taken by exposing one-half of the slit to the light after passing through the absorption cell, and the other half to the light from copper and nickel arcs.

Meggers⁵ values for the wave length of the copper lines and Meggers and Kiess⁶ values of the nickel lines in the near infra-red region were taken as standards for measurement. The dispersion of the spectroscope as used was approximately 39.8 Å. per millimeter. Measurements of the plates were made in the usual manner on a comparator reading to 0.001 mm.

Discussion of Results

The results given in Table I are the means of many measurements made upon the center of the absorption bands photographed on two plates for each substance, one with the longer and the other with the shorter cell. The results are believed to be accurate to within ± 5 Å.

Table I gives the wave lengths in Å. units and the wave numbers ($1/\lambda$) in cm.^{-1} reduced to vacuum as obtained from Kayser's "Tabelle der Schwingungszahlen."

TABLE I

WAVE LENGTHS AND WAVE NUMBERS OF ABSORPTION BANDS OF BENZENE DERIVATIVES

	λ (Å)	$1/\lambda$ (cm.^{-1})		λ (Å)	$1/\lambda$ (cm.^{-1})
Benzene	8741	11437	<i>m</i> -Xylene	8793	11370
Toluene	8758	11415	<i>p</i> -Xylene	8808	11350
Ethylbenzene	8772	11397	Diethylbenzene ^a	8799	11362
<i>o</i> -Xylene	8781	11385	Mesitylene	8844	11304

^a Mixture of *m*- and *p*-diethylbenzene.

Table I shows that there is a progressive shift of the absorption bands toward the longer wave lengths and hence a decrease in the frequencies with the addition of methyl and ethyl groups to the benzene ring.

Table II shows the frequencies ($\nu \times 10^{-11}$) and the difference produced by quantum addition of ethyl and methyl groups, respectively.

⁵ Meggers, *Bur. of Standards, Bull.*, 14, 385 (1918-19).

⁶ Meggers and Kiess, *ibid.*, 14, 649 (1918-19).

TABLE II
FREQUENCIES OF ABSORPTION BANDS AND THEIR DIFFERENCES

	Benzene	Ethyl- benzene	Diethyl benzene	Toluene	Xylene ^a	Mesitylene
Frequency $\times 10^{11}$	3431	3419	3409	3424	3410	3391
Difference	...	12	10	7	14	19

^a Mean of xylenes.

Table III shows that the frequency depends on the position of the methyl groups in the xylenes.

TABLE III
FREQUENCIES OF THE ABSORPTION BANDS OF THE XYLENES AND THEIR DIFFERENCES

Xylene	<i>o</i>	<i>m</i>	<i>p</i>
$\nu \times 10^{11}$	3415	3411	3405
Diff.	...	4	6

While there is probably no justification for extending the Bjerrum-Schwarzschild theory of band spectra to liquids, yet it is of some interest to note that, with the resolving power employed, no doubling of the bands nor any sign of fine structure was observed on any of the photographic plates.

The effect of the addition of methyl or ethyl groups on the molecular forces of the benzene ring is not well understood. However, if the effect is small compared to the effect of the added mass one would expect on a theory such, for example, as that proposed by Debye that the change in the frequency would be inversely proportional to some function of the added mass. The results above are at least in qualitative agreement with such a theory.

In this connection the following data given by Ellis⁷ are of interest.

DISPLACEMENT OF A 14μ BAND IN THE SPECTRA OF THE BENZENE DERIVATIVES

Benzene	Toluene	<i>o</i> -	-Xylene- <i>m</i> -	<i>p</i> -	Mesitylene
14.1	13.85	13.55	12.95	12.55	11.95

These results taken from Coblenz' curves show that in these bands which Ellis attributes to the carbon-carbon bond, the wave lengths shift progressively toward the shorter wave lengths as methyl groups are added, which is in the opposite direction to the results recorded above.

In conclusion, we wish also to report that plates were taken of the absorption spectrum of benzene produced by a cell of 80 cm. length. No absorption was found at wave lengths 0.835μ and 0.760μ , but a band clearly appeared at 7134 \AA . With this length of cell the band at 7134 \AA . is easily observed visually.

Summary

By means of a grating and plates sensitized with neocyanine, absorption bands of benzene and of some of its derivatives have been photographed

⁷ Ref. 4, p. 313.

and their wave lengths measured. The results show a progressive shift of the bands toward lower frequencies as methyl and ethyl groups are added. There is also a shift due to the position of the methyl group in the xylenes.

With a cell 80 cm. in length, benzene shows an absorption band at 7134 Å.

THE CHEMISTRY OF LIGNIN. I. LIGNIN FROM CORN COBS

By MAX PHILLIPS

RECEIVED APRIL 27, 1927

PUBLISHED AUGUST 5, 1927

In spite of the extensive literature on lignin the chemistry of this product remains obscure.¹ Nothing definite is known about its constitution, although various formulas have been proposed, among which may be mentioned that of Cross and Bevan² for lignin ("lignone") from jute, and those of Green,³ Klason⁴ and Schrauth.⁵ Most of these formulas have little definite chemical evidence in their support. That of Schrauth is admittedly speculative, although this investigator has endeavored, with some success, to correlate the conflicting data on lignin found scattered in the literature. The difficulty in deducing a constitutional formula for lignin is primarily due to the fact that as yet no method has been developed for the isolation of lignin in the pure state, nor is there any method known by which its purity may be gaged. The usual criteria of purity cannot, of course, be applied. The problem as to whether lignin is a homogeneous substance or a mixture of closely related chemical substances, therefore, remains unsolved. This has been further complicated by the fact that various investigators have obtained their lignin from different sources and by different methods. It has been obtained from (1) sulfite or soda and sulfate liquors resulting from the preparation of paper pulp from wood, (2) wood treated with 64-72% of sulfuric acid, (3) wood or similar lignin-containing plant material treated with saturated

¹ An extensive review of the literature is found in a recent monograph by Walter Fuchs, "Die Chemie des Lignins," Julius Springer, Berlin, 1926. Hawley and Wise, in their monograph on "The Chemistry of Wood," The Chemical Catalog Co., New York, 1926, give a critical review of our present knowledge of the chemistry of lignin, particularly that obtained from wood. An excellent résumé of the literature is given in a paper by Zhereboff [*Paper Trade J.*, **86**, No. 27, 47 (1925)].

hydrochloric acid (so-called Willstätter lignin),⁶ (4) lignin-containing substance digested with 10% of sodium hydroxide solution at 130° (Powell and Whittaker),⁷ or with 1.5% of aqueous or 2% of alcoholic sodium hydroxide solution at room temperature (Beckmann, Liesche and Lehmann).⁸

The lignin fraction described in this paper was prepared by the alcoholic sodium hydroxide method of Beckmann, Liesche and Lehmann, as this treatment was considered least likely to bring about any drastic changes in its composition. It would hardly be expected that the lignin obtained by the hydrochloric or sulfuric acid methods, or from the sulfite or soda and sulfate liquors, would be identical with that which occurs in the plant substance. That these drastic treatments do bring about marked changes in the composition of the lignin has been pointed out by a number of investigators.^{5,9} On the other hand, the lignin obtained from flax shoves by the method of Powell and Whittaker and from winter rye straw by that of Beckmann, Liesche and Lehmann appears to have been a fairly homogeneous substance. The results obtained in this investigation agree closely with those of Beckmann, Liesche and Lehmann and of Powell and Whittaker. Recognizing that in the absence of any criteria of purity all data must be interpreted with considerable caution, the results obtained, nevertheless, warrant the conclusion that the lignin fraction from corn cobs is a fairly homogeneous substance or a mixture of closely related isomers. The fact that the results on lignin from corn cobs agree fairly closely with those of Powell and Whittaker, who used a somewhat different method for obtaining the lignin from flax shoves, is certainly noteworthy. All the data obtained agree fairly closely with the formula $C_{40}H_{46}O_{16}$ for lignin from corn cobs. (The formula given by Beckmann, Liesche and Lehmann for lignin from winter rye straw is $C_{40}H_{44}O_{16}$, and that of Powell and Whittaker for lignin from flax shoves, $C_{45}H_{48}O_{16}$.) It contains three methoxyl groups and at least four hydroxyl groups. No carboxyl groups are present. The acidity is due to phenolic hydroxyl groups.

There has been a great deal of discussion¹⁰ on the question of whether pentosans or furfural-yielding bodies may be considered as part of the structural arrangement of the lignin molecule or as an impurity associated with lignin. The lignin fraction obtained from corn cobs, even after prolonged distillation with 12% hydrochloric acid, gave no test for furfural

in the distillate. The absence of pentosans or furfural-yielding bodies in the lignin fraction from corn cobs must then be assumed.

Experimental Part

Isolation of Lignin.—One thousand g. of corn cobs, cut in small pieces, was treated with 4 liters of 2% alcoholic sodium hydroxide solution (made by dissolving 80 g. of sodium hydroxide in 1600 cc. of water and making this up to a volume of 4 liters with 95% ethanol) and allowed to stand at room temperature for three days. The yellow alcoholic solution was decanted off, the cobs were pressed out, and the liquid was added to the solution obtained by decantation. This was filtered, neutralized with hydrochloric acid and concentrated by distilling on the water-bath under reduced pressure. Hydrochloric acid was added to the concentrated liquid, whereupon the lignin separated as a light yellow gum. This was filtered off, washed free from acid, and dried at 80° under reduced pressure. The yield was 3.49% of the weight of cobs taken. The lignin was a light yellow, amorphous powder. It reduced Fehling's solution. A portion of the lignin obtained as described above was redissolved in cold, dil. sodium hydroxide solution and then reprecipitated with hydrochloric acid. A carbon and hydrogen determination made on this fraction and upon the original batch showed no material change in composition. Two typical analyses are given below:

Anal. Subs., 0.2070, 0.2065; CO₂, 0.4637, 0.4638; H₂O, 0.1095, 0.1080. Found: C, 61.08, 61.24; H, 5.91, 5.85.

A molecular-weight determination made upon the substance by the boiling-point method, using glacial acetic acid as the solvent, gave the following results.

Mol. Wt. Subs., 0.3787, 0.3633, 0.3445; solvent, W, 24.1160, 24.2970, 24.3570; Δt , 0.065, 0.060, 0.060. Found: M, 753, 777, 735; mean, 755.

From a consideration of all the data, the formula C₄₀H₄₆O₁₆ has been assigned as the most probable one for this lignin fraction from corn cobs. The molecular weight and the percentage composition calculated for a compound of this formula are: M, 782.5; C, 61.36; H, 5.92; O, 32.72.

A methoxyl determination made on the lignin using the Zeisl and Fanto¹¹ method gave the following results.

Methoxyl. Subs., 0.3000, 0.3000, 0.3000, 0.3000; AgI, 0.2766, 0.2800, 0.2712, 0.2705. Calcd. for C₄₁H₄₇O₁₅(OCH₃)₁: CH₃O, 11.9. Found: 12.1, 12.3, 11.9, 11.9.

A 2g. sample of the lignin was distilled with 12% hydrochloric acid, following the A. O. A. C. method¹² for the determination of pentosans. The distillate gave a negative test for furfural with aniline acetate test paper and no precipitate with the phloroglucinol reagent.

Acetylation of Lignin.—The acetylation of the lignin was carried out, following the method of Powell and Whittaker.^{7a} Ten g. of lignin was treated with 20 cc. of acetic anhydride, a few drops of concd. sulfuric acid were added, and the mixture was heated on the steam-bath for one hour. After cooling, it was poured into ice water, and the precipitate filtered off, and washed with cold water until the washings were free from acid. The product was dried over sulfuric acid in a vacuum desiccator. It was obtained as a brown, amorphous powder, insoluble in cold, dil. alkali, indicating that the

¹¹ Houben, "Die Methoden der Organischen Chemie," Vol. III, Georg Thieme, Leipzig, 1923, p. 144.

¹² "Official and Tentative Methods of Analysis of the Association of Official Agricultural Chemists," Association of Official Agricultural Chemists, Washington, D. C., 1925.

acidity of the lignin is due to phenolic hydroxyl groups. The acetyl determination was made following the method of Perkin.¹⁸

Acetyl. Subs., 1.0000, 1.0000, required 8.06 cc., 8.08 cc. of 0.5*N* KOH. Subs., 0.3000, 0.3000; AgI, 0.2377, 0.2370. Calcd. for $C_{47}H_{38}O_{13}(CO_2CH_3)_4(OCH_3)_3$: CH_3CO , 18.1; CH_3O , 9.8. Found: CH_3CO , 17.3, 17.4; CH_3O , 10.4.

Chlorination of Lignin.—The directions given by Powell and Whittaker^{7a} for the chlorination of lignin were followed. Ten g. of lignin was suspended in 80 cc. of carbon tetrachloride, and a slow stream of dry chlorine gas was passed in until no more hydrogen chloride was given off from the reaction mixture. The product was filtered off and dissolved in concentrated acetone solution (two volumes of acetone and one volume of water). The chlorolignin was precipitated by pouring the solution into dil. hydrochloric acid. It was filtered off, washed free from acid and dried over sulfuric acid in a vacuum desiccator.

Anal. Subs., 0.3072, 0.2214, 0.2235; AgCl, 0.3985, 0.2880, 0.2903. Calcd. for $C_{46}H_{36}O_{13}Cl_{10}$: Cl, 31.45. Found: Cl, 32.09, 32.17, 32.13.

Summary

The results of a chemical study of a lignin fraction from corn cobs indicate that the lignin is a fairly homogeneous substance or a mixture of closely related isomers. All the results agree closely with the formula $C_{40}H_{46}O_{16}$ for lignin from this source. The presence of four hydroxyl groups capable of being acetylated and of three methoxyl groups has been shown.

The results obtained on lignin from corn cobs are in close agreement with those obtained by Beckmann, Liesche and Lehmann on lignin from winter rye straw and with the results of Powell and Whittaker on lignin from flax shoves.

ALICYCLIC DERIVATIVES OF RESORCINOL

BY RALPH H. TALBOT¹ WITH ROGER ADAMS

RECEIVED MAY 6, 1927

PUBLISHED AUGUST 5, 1927

The search for a superior substance which will exert a bactericidal activity against the organisms of the urinary tract has led recently to the discovery of *n*-hexyl-resorcinol by Dohme, Cox and Miller.² Although this substance has proved disappointing in its clinical results as compared with expectations drawn from preliminary work,³ nevertheless it presents an interesting field of bactericidal compounds.

The original investigators prepared various types of alkyl resorcinols,

¹⁸ Perkin, *Proc. Chem. Soc.*, 20, 171 (1904).

¹ This communication is an abstract of a portion of a thesis submitted by Ralph H. Talbot in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

² Dohme, Cox and Miller, *THIS JOURNAL*, 48, 1688 (1926).

³ Leonard, *J. Am. Med. Assoc.*, 83, 2005 (1924).

and found *n*-hexyl-resorcinol to be the most effective. Klarmann⁴ has extended the field to benzyl- and β -phenylethyl-resorcinols and to certain dialkyl-resorcinols, but these compounds possess lower phenol coefficients than hexyl-resorcinol. Twiss⁵ has described caproyl-resorcinol.

This investigation has had as its object the preparation of certain alicyclic derivatives of resorcinol, in particular hexahydrobenzyl-resorcinol (I), β -cyclohexylethyl-resorcinol (II), and cyclopentylmethyl-resorcinol (III).

These compounds were deemed worthy of study because of the fact that the presence of an alicyclic grouping in compounds prepared in connection with another field of work caused a marked increase in bactericidal action of a certain type as compared with the corresponding open-chain compounds.

The method of preparation was similar to that previously used for this type of compound, namely, the condensation of hexahydrobenzoic acid, cyclopentane-carboxylic acid and cyclohexyl-acetic acid with resorcinol in the presence of zinc chloride to obtain the corresponding ketones. The ketones were then reduced by the method of Clemmensen in order to convert the ketone carbonyl to a methylene group.

The three new resorcinol derivatives all have a high phenol coefficient but lower than that of *n*-hexyl-resorcinol.

Experimental Part

The procedure for preparing the ketones and the reduction of the ketones was exactly the same as that described by Dohme, Cox and Miller.²

Cyclohexyl-acetic acid was prepared as described by Hiers and Adams.⁶

Cyclopentane-carboxylic acid was prepared by the action of carbon dioxide on cyclopentylmagnesium bromide, followed by hydrolysis. The preparation of the Grignard, the addition of the carbon dioxide and the hydrolysis were carried out in accordance with the general procedure for

POLYHYDROXY-METHYLANTHRAQUINONES.

IX. CONTRIBUTION TO THE STRUCTURE OF RUBIADIN

BY FLORENCE D. STOUDER¹ WITH ROGER ADAMS

RECEIVED MAY 6, 1927

PUBLISHED AUGUST 5, 1927

Rubiadin is one of the pigments of madder² in which it occurs as a glucoside. Its monomethyl ether has been isolated from *morinda longiflora*^{3a} and *morinda citrifolia*.^{3b} Rubiadin was first isolated by Schunck and Marchlewski⁴ who, after analysis and molecular-weight determinations, assigned to it the composition of a dihydroxy-methylantraquinone. By oxidation it yielded phthalic acid thus indicating that all of the groups present were in the same ring. There are thus six possible isomers, 1,2-dihydroxy-3-methyl-, 1,2-dihydroxy-4-methyl-, 1,4-dihydroxy-2-methyl-, 2,3-dihydroxy-1-methyl-, 1,3-dihydroxy-2-methyl- and 1,3-dihydroxy-4-methylantraquinone. The first three are known substances and do not resemble rubiadin; the fourth is not known, but with two adjacent hydroxyl groups it should have reactions similar to those of alizarin and hystazarin, reactions which it does not possess. Rubiadin has, therefore, very probably either the fifth (I) or sixth (II) formula, and is a purpuroxanthin derivative as is indicated also from its color reactions—red with alkali and yellow with concd. sulfuric acid.

Schunck and Marchlewski synthesized the 1,3-dihydroxy-2-methylantraquinone and showed that it resembled rubiadin very closely in its color reactions and had the same melting point, 290°. The diacetate of rubiadin, however, melted at 225°, and that of the synthetic product at 217°. As a consequence these investigators assumed rubiadin to be the 1,3-dihydroxy-4-methylantraquinone.

The monomethyl ether of rubiadin (m. p., 290°), as isolated by Barrowcliff and Tutin from *morinda longiflora*, formed on demethylation a dihydroxy-methylantraquinone (m. p., 290°), whose diacetate melted

¹ This communication is an abstract of a portion of a thesis submitted by Florence D. Stouder in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Chemistry in the Graduate School at the University of Illinois.

² Perkins and Everest, "Natural Organic Coloring Matters," Longmans, Green and Co., London, 1918.

³ (a) Barrowcliff and Tutin, *J. Chem. Soc.*, 91, 1909 (1907). (b) Simonsen, *ibid.*, 117, 561 (1920).

⁴ Schunck and Marchlewski, *ibid.*, 63, 969, 1137 (1892); 65, 182 (1894).

at 225°. Although these are the melting points of rubiadin and its derivative, these investigators assigned to the compound the structure of the monomethyl ether of 1,3-dihydroxy-2-methylantraquinone, in spite of Schunck and Marchlewski's conclusions.

In this investigation the 1,3-dihydroxy-4-methylantraquinone (II) and its derivatives have been synthesized and have been shown not to be identical with rubiadin and its derivatives.

	Rubiadin M. p., °C.	1,3-dihydroxy-4-methyl- anthraquinone M. p., °C.
Anthraquinone	290	251
Dimethyl ether	181	162
Diacetate	225	176.5

The only conclusion that can be drawn is that rubiadin is 1,3-dihydroxy-2-methylantraquinone and that Schunck and Marchlewski did not obtain the pure diacetate of 1,3-dihydroxy-2-methylantraquinone synthetically, and consequently found a discrepancy between the melting point of their product and that of the corresponding derivative of the natural product.

The 1,3-dihydroxy-4-methylantraquinone was prepared by condensing phthalic anhydride with 2,4-dichlorotoluene to give 2,4-dichloro-5-methylbenzoyl-*o*-benzoic acid (III), which was converted with sulfuric acid to the corresponding anthraquinone (IV). Upon long treatment with sodium methylate the halogens were replaced by methoxyl groups (V) and the free hydroxyl derivative was obtained by the action of hydrobromic acid.

The synthesis of 1,3-dihydroxy-2-methylantraquinone is now being studied.

Experimental Part

2,4-Dichlorotoluene.—To 90 cc. of cuprous chloride solution (prepared according to the method of Marvel and McElvain⁵) was added a solution of 20 g. of 2,4-diaminotoluene hydrochloride in 20 g. of concd. hydrobromic acid and 100 cc. of water. The solution was brought to a boil in a flask fitted with a mercury seal stirrer and a reflux

⁵ Marvel and McElvain, "Organic Syntheses," John Wiley and Sons, Inc., New York, Vol. III, 1925, p. 33.

condenser and then without further heating, 180 cc. of 10% sodium nitrite solution was added, drop by drop. When all was added the mixture was steam distilled and the dichlorotoluene washed with sodium hydroxide solution, water, and then distilled in a vacuum; yield, 11.6 g. of product boiling at 195°. The chief difference between these directions and those which appear in the literature⁶ is that a much more dilute solution is employed and a tight container used to prevent volatilization.

2,4-Dichloro-5-methyl-benzoyl-*o*-benzoic Acid. III.—The general procedure used was that described by Fieser⁷ for preparing 4-methyl-benzoyl-*o*-benzoic acid. After condensing for eight hours 20 g. of phthalic anhydride, 69 g. of 2,4-dichlorotoluene and 50 g. of anhydrous aluminum chloride, there was obtained a thick, viscous substance which, however, readily crystallized from hot toluene and when pure, melted at 140°; yield, about 60%.

Anal. Subs., 0.1000: 2.15 cc. of 0.1530 *N* NaOH. Calcd. for $C_{18}H_{10}O_3Cl_2$: neut. equiv. 309. Found: 304.

2,4-Dichloro-1-methylanthraquinone. IV.—A mixture of 20 g. of 2,4-dichloro-5-methyl-benzoyl-*o*-benzoic acid with 4 g. of boric acid and 400 cc. of concd. sulfuric acid was heated on a water-bath for two hours. Upon pouring into water, there was obtained 7.5 g. of product which upon purification from chloroform formed bright yellow crystals and melted at 155°.

Anal. Subs., 0.2000; 13.7 cc. of 0.1 *N* AgNO₃. Calcd. for $C_{16}H_8O_2Cl_2$: Cl, 24.4. Found: 24.3.

2,4-Dimethoxy-1-methylanthraquinone. V.—A solution of sodium methylate was prepared by adding as much sodium to 250 cc. of absolute methyl alcohol as would dissolve in it at ordinary temperature. To this was added 6 g. of pure 2,4-dichloro-1-methylanthraquinone and the mixture heated under a reflux condenser on a water-bath for 24 hours. Water was then added, the methyl alcohol boiled off and the crude product filtered and dried. Upon purification from chloroform, it formed yellow needles melting at 162°.

Anal. Subs., 0.1500; CO₂, 0.3949; H₂O, 0.0611. Calcd. for $C_{17}H_{10}O_4$: C, 72.4; H, 4.98. Found: C, 72.0; H, 4.6.

2,4-Dihydroxy-1-methylanthraquinone.—The 2,4-dimethoxy-1-methylanthraquinone was refluxed for 12 hours in a mixture of constant-boiling hydrobromic and glacial acetic acids. The product was purified from benzene and then formed pale yellow needles, melting at 251°.

Anal. Subs., 0.1000; CO₂, 0.2612; H₂O, 0.0360. Calcd. for $C_{16}H_{10}O_4$: C, 70.84; H, 3.97. Found: C, 71.26; H, 4.03.

2,4-Diacetoxy-1-methylanthraquinone.—By refluxing 1 g. of 2,4-dihydroxy-1-methylanthraquinone with 20 cc. of acetic anhydride and 2 g. of freshly fused sodium acetate, there was obtained upon treatment with water the diacetyl derivative, which was purified by crystallization from acetic acid. It formed yellow needles melting at 176.5°.

Summary

The synthesis of 1,3-dihydroxy-4-methylanthraquinone has been completed and the substance has been shown not to be identical with rubiadin.

BOA CONSTRICTOR FAT

BY ROBERT H. KERR

RECEIVED MAY 9, 1927

PUBLISHED AUGUST 5, 1927

I. Source and Preparation of Material

The material used was obtained from the carcass of a large boa constrictor which had died from natural causes at the National Zoological Park, and consisted of egg-shaped masses of fat located along the intestines. These were chopped into fine bits, a small amount of sodium bicarbonate was added to the hashed mass and the whole heated over a free flame with constant stirring to a temperature of 125°. After being held at this temperature for a few minutes the rendered fat was filtered through a large folded filter. The rendered fat was a clear liquid of faint yellow color, and a peculiar and somewhat unpleasant odor. When cold it was a soft, yellowish solid.

II. Analysis of the Rendered Fat

M. p.	28.5°	Specific gravity at 100° (water	
Iodine no. (Hanus)	79.43%	at 15.5 = 1)	0.8629
Iodine no. of liquid fatty acids	113.17%	Saponification no.	196.83%
Refractive index at 40°	1.4619	Free fatty acids	0.17%

Identification of Unsaturated Acids

(a) **Highly Unsaturated Acid.**—The liquid fatty acids were dissolved in a mixture of equal parts of glacial acetic acid and ether, and bromine was added to the development of a permanent red color. A white precipitate appeared at once. This was filtered off and washed with cold ether. It proved to be insoluble in boiling ether, but was sparingly soluble in boiling benzene. It did not exhibit a definite melting point but turned brown and decomposed at 180–190°. As the amount of the material was not sufficient for further investigation, a larger amount was prepared by brominating the mixed fatty acids obtained from 10 g. of the fat. The precipitate was found to be insoluble in ether, alcohol and chloroform, and sparingly soluble in hot benzene. It decomposed at 180–190°. Analysis showed that it contained 70.15% of bromine. The bromine content corresponds to that of octobromostearic acid, indicating the presence of an acid corresponding to the formula $C_{18}H_{28}O_2$.

(b) **Linolic Acid.**—After the removal of the precipitate of octobromostearic acid, the acetic acid and excess of bromine were removed from the ether solution of the brominated acids by shaking in a separatory funnel with a solution of potassium iodide and sodium thiosulfate and then washing thoroughly with water. The ether was then evaporated and the residue dried in a vacuum. The dried residue was treated with successive small portions of ice-cold petroleum ether and the insoluble portion carefully washed with cold petroleum ether and finally dried. The residue was white and granular. It exhibited all of the characteristic properties of tetrabromostearic acid, including melting point and neutralization value, thus showing the presence of linolic acid.

(c) **Oleic Acid.**—The presence of oleic acid was demonstrated by examination of the residue remaining after the removal of the octo- and tetrabromostearic acids from

the brominated liquid acids. The physical characters, solubility and bromine content of this residue corresponded to those of dibromostearic acid.

Solid Acids

The separation of liquid and solid fatty acids by the lead salt-ether method gave 33.13% of solid acids, melting at 41.2° and having a mean molecular weight of 282.96, the latter being calculated from the neutralization value.

By fractional precipitation with magnesium acetate and crystallization from alcohol, two fractions melting at 64.0 and 58.0°, respectively, were obtained. Neutralization gave a calculated mean molecular weight of 281.7 for the fraction melting at 64.0° and of 264.6 for the portion melting at 58.0°. The quantity of material was not sufficient to permit the preparation of pure acids.

Summary

A specimen of boa-constrictor fat was prepared and examined. The unsaturated acids were found to consist of oleic acid, linolic acid and a highly unsaturated acid which formed an insoluble bromo addition product, tentatively identified as octobromostearic acid. The saturated acids evidently consisted of palmitic and stearic acids.

SOME HALOGEN AND HYDROXYL DERIVATIVES OF 2-OXO-DIHYDRO, 2-OXO-HEXAHYDRO-INDOLE-3-PROPIONIC ACID, AND OF 2-OXO-HEXAHYDROBENZOFURAN-3-PROPIONIC ACID

BY EDWARD C. KENDALL AND ARNOLD E. OSTERBERG

RECEIVED MAY 13, 1927

PUBLISHED AUGUST 5, 1927

The preparation of 2-oxo-hexahydro-benzofuran-3-propionic acid has been described.¹ If this compound is treated in dilute aqueous hydrobromic acid with bromine, a monobromo derivative can be separated (I). If a solution of the sodium salts of the lactone is treated with bromine a monobromo derivative of the lactone crystallizes from solution (II). These two monobromo derivatives are not identical; the one prepared from the sodium salt has the percentage composition of a monobromo derivative of the lactone. However, it is a neutral compound possessing no acidic properties although the carboxyl group in the original lactone requires one equivalent of sodium hydroxide for its neutralization.

¹ Kendall, Osterberg and MacKenzie, *THIS JOURNAL*, **48**, 1384 (1926). The indole nucleus is referred to by the following numbers, and the open pyrrolidine ring compounds are numbered in the usual manner for aromatic derivatives.

The monobromo derivative prepared in dilute hydrobromic acid contains a carboxyl group, and it is much more soluble than the one which shows no acidic properties. It can be crystallized from xylene, but if the solution is refluxed for about an hour water is given off and, after cooling, crystals separate which are identical with the neutral monobromo derivative (II). The percentage composition of the monobromolactone with acidic properties (I) corresponds to that of a monobromo derivative of the original lactone with the addition of one molecule of water.

Both of these bromolactones give the same hydroxyl derivative when treated with sodium hydroxide. This hydroxyl derivative also exists in two forms, acidic and neutral, which corresponds to the bromolactone. If the hydroxyl derivative is heated with a slight excess of sodium hydroxide, two equivalents of alkali are required for the neutralization of the product. The terminal carboxyl and the carboxyl group of the lactone both exist in free form (VI). If the disodium salt is treated with an equivalent amount of mineral acid and the solution is allowed to stand at room temperature, one equivalent of carboxyl titration disappears and then only one equivalent of sodium hydroxide is required for its neutralization; this is evidence for the closure of the lactone ring in a slightly acid solution (IV). If this solution is now boiled, the remaining acid group reacts in such a manner that the resulting solution is neutral (V).

Identification of these compounds could not be carried out until the position occupied by the bromine was determined. Oxidation with permanganate or with ozone did not give products which were useful for the identification of the compound. Further bromination did not result in the breaking of the lactone and did not give any products which were of help. Fusion with sodium hydroxide caused a deep-seated reaction and the products of the alkaline fusion indicate the position of the bromine. When the disodium salt of the hydroxyl compound is heated with concd. sodium hydroxide in a distilling flask to 170°, a volatile oil is given off. This is soluble in water, but can be thrown out of solution with potassium carbonate. It is only slightly soluble in ether and when recrystallized from benzene it proved to be the *trans*-form of cyclohexane glycol.² In the sodium hydroxide fusion were found large amounts of succinic acid. Only traces of acetic acid resulted from the fusion. If the heating was carried on at a higher temperature valeric acid was found in the fusion melt; no acid-insoluble product resulted.

These reactions indicate that the bromine occupied Position 3 and that the ketocyclohexane-hydroxyl-glutaric acid had rearranged, giving cyclohexane glycol (VII). The resulting α -hydroxyl-glutaric acid was broken down into carbon dioxide and succinic acid. No butyrolactone was formed, but the succinic acid was a high percentage of the amount

² Bedos, *Compt. rend.*, **183**, 750 (1926).

theoretically possible. Rupture of the cyclohexane ring probably explains the formation of the valeric acid at a high temperature.

After the identification of the position of the hydroxyl group in the lactone, it became necessary to explain the presence of the molecule of water in Form I and the loss of the carboxyl group in the neutral Form II. When two equivalents of bromine react with the sodium salt of the lactone one equivalent of bromine combines with the lactone, and the second equivalent is present in the solutions as sodium bromide. A yield of 90% of the monobromolactone was secured. This is conclusive evidence that the molecule of water is not present as an hydroxyl formed by oxidation of the lactone; still further evidence for this is the fact that the monobromolactone can easily be reduced to the original lactone, which separates without a molecule of water or an hydroxyl group.

When the monobromolactone is heated in xylene the resulting compound, which is neutral (II), is not formed by the loss of hydrobromic acid, but is formed by the loss of water. In connection with the problem of explaining these reactions, we take pleasure in acknowledging a suggestion from E. P. Kohler, who says, "First there is a shift of the double linkage from Δ -7a, 3a to Δ -3, 3a, as shown by Formulas A and B. This is the usual change of an unconjugated to a conjugated system of double bonds—probably the most general property of β,γ -unsaturated acids." Next, when the lactone B is treated with bromine in the presence of water, bromine does not substitute but hypobromous acid is added. "This is what invariably happens when an α,β -unsaturated acid or any of its derivatives or α,β -unsaturated ketones are treated with bromine in the presence of water or bases. In such cases bromine goes into the alpha position and hydroxyl into the beta."

The double bond in 2-oxo-hexahydrobenzofuran-3-propionic acid is very resistant to reduction or to the addition of hydriodic or hydrobromic acids and bromine. It reacts slowly with potassium permanganate. However, it seems most probable that the course of the bromination as suggested by Kohler is through the addition of hypobromous acid to the double bond which occupies Position 3,3a in the lactone. Closure to the lactone between the terminal carboxyl and the hydroxyl group on Position 3a explains the loss of acidic properties in the neutral Form II.

Another reaction which indicates that the disodium salt of the 3-hydroxyl derivative exists with hydroxyl groups on 3a and 7a, is the impossibility of forming the 3-hydroxyl-lactam from the 3-hydroxyl-lactone. Ketocyclohexane-glutaric acid will react with ammonia, giving a practically quantitative yield of the corresponding lactam, but when the 3-hydroxyl or the disodium salt of 3-hydroxyl-2-oxo-hexahydrobenzofuran-3-propionic acid is treated with ammonia no trace of lactam is produced. This is evidence that the ketone group is not present on Carbon 7a and that the structure probably is the 3,3a,7a-trihydroxyl derivative.

Conclusive proof of the structure of 2-oxo-hexahydrobenzofuran-propionic acid is furnished by the effect of ozone on this compound. Ozone reacts with this lactone in glacial acetic acid, with the formation of succinic acid. This decomposition could not occur unless the bond lay between Carbons 3 and 3a. Finally, if the 3-bromo-3a-hydroxyl derivative is treated with ozone no decomposition occurs. This is in agreement with the structure assigned, that is, a dihydroxyl derivative of octohydrobenzofuran.

The neutral form (II) of the monobromo derivative contains a δ -lactone, which is made by loss of water. If, however, the monobromolactone (I) is dissolved in a small amount of alcohol and water, and sodium hydroxide is added, it will remove most of the bromine attached to the lactone, and crystals separate from the solution (III). These crystals are neutral and are identical with the γ -lactone of the 3,3a-dihydroxyl derivative of the lactone (V). This is evidence that the second lactone grouping of this compound was made by loss of hydrobromic acid between the terminal carboxyl and the bromine attached to Carbon 3.

When the dihydroxyl derivative of the lactone (IV) is boiled in the presence of a small amount of mineral acid the γ -lactone derivative (V) separates from solution, and since this is identical with the compound made by loss of hydrobromic acid from the monobromolactone, the position of the second lactone ring in this compound probably is between the terminal carboxyl and the hydroxyl group attached to Carbon 3 (V). Still further evidence for this is the failure to substitute the hydroxyl group giving a lactone with halogen in Position 3 when the lactone derivative is treated with phosphorus oxychloride, phosphorus pentachloride and thionyl chloride.

These reactions indicate that the terminal carboxyl tends to form a lactone with the hydroxyl group in Position 3a if the hydrogen in Position 3 is substituted with bromine, but if an hydroxyl group is attached to Carbon 3 the terminal carboxyl forms a lactone with it.

The monobromolactone (I) reacts in a peculiar manner with sodium hydroxide. This is shown as follows. If to 100 mg. of the bromolactone 3.6 cc. of 0.1 *N* sodium hydroxide solution is added, the solution still reacts acid with phenolsulfonephthalein as indicator. If a total of 4 cc. is slowly added, all acidic properties are neutralized and the indicator becomes pink. At this hydroxyl-ion concentration, a second reaction is brought about and the alkalinity of the solution rapidly increases. Sulfuric acid, 0.1 *N*, can now be added until the solution reacts neutral, and this is soon followed by the liberation of more sodium hydroxide until a total of approximately 0.6 cc. of 0.1 *N* sulfuric acid has been added. Determination of the sodium bromide in the solution shows that only 1.9 cc. of 0.1 *N* sodium bromide is present; therefore, the increase in the alkalinity of the solution was due to closure of the lactone between the

terminal carboxyl and the hydroxyl group either on 3 or 3a. The total amount of alkali neutralized was 3.5 cc. of 0.1 *N*. The bromide removed was 1.9 cc., 0.1 *N*, which leaves 1.6 cc. of carboxyl neutralized with sodium hydroxide.

The relation between the sodium hydroxide required and the hydrobromic acid neutralized is evidence of lactone formation brought about by the sodium hydroxide. This was confirmed by separation of crystals of the γ -lactone of the 3,3a-dihydroxyl derivative (V). If, however, the sodium hydroxide first removes the bromine from Carbon 3, replacing it with hydroxyl, there is no evidence that the terminal carboxyl forms a lactone with an hydroxyl group on either Carbon 3 or 3a, at room temperature.

2-Oxo-hexahydro-indole-3-propionic acid¹ reacts with bromine in a manner entirely similar to the corresponding lactone. If the bromine is added to an aqueous solution of the lactam, the monobromolactam separates (VIII) and if the lactam is present as a monosodium salt in a solution containing sodium acetate the δ -lactone of the monobromo derivative separates (IX). It is, however, much easier to open the δ -lactone of the bromolactam than of the bromolactone. The last-mentioned compound can be heated in concd. hydrobromic acid without opening the second lactone ring. With the bromolactam the presence of even a small amount of mineral acid will bring about this reaction at room temperature. For each equivalent of bromine added to the lactam one equivalent of sodium bromide is formed. The bromine can be reduced from the monobromolactam with formation of the original material. Treatment with sodium hydroxide replaces the bromine forming the dihydroxyl derivative which exists in two forms (XI and XII) corresponding to the bromolactam.

Fusion of the 3,3a-dihydroxyl-lactam with sodium hydroxide decomposes this compound giving products similar to those obtained from the corresponding hydroxyl-lactone with sodium hydroxide. Succinic and acetic acids were identified, and an amine which precipitates from ether solution with carbon dioxide. Its chemical properties closely simulate those of *o*-aminocyclohexanol,² but insufficient material was obtained for its identification. The formation of this compound would correspond to the production of cyclohexane glycol from the hydroxyl-lactone. In addition to these compounds a volatile, crystalline substance was obtained which appeared to be a dimolecular derivative of the hydro-indole, $C_{11}H_9N$. No valeric or other acid-insoluble products were formed. These reactions are evidence that the hydroxyl groups are attached to Carbons 3 and 3a, and that the dihydroxyl-lactam decomposes in two ways, one giving succinic acid and a derivative of cyclohexane, the other giving a hydro-indole

¹ Osterberg and Kendall, *THIS JOURNAL*, **42**, 2616 (1920). Brunel, *Ann. chim. phys.*, **6**, 253 (1905).

derivative and malonic acid which decomposes into carbon dioxide and acetic acid.

In the lactone of the dihydroxyl derivative of the lactam (XII) the terminal carboxyl is probably combined with the hydroxyl group on Carbon 3. Evidence for this is the impossibility of forming the 3-halogen derivative of the lactam by treatment of the lactone of the dihydroxyl-lactam with phosphorus pentachloride, phosphorus oxychloride or thionyl chloride. Further evidence for this is the preparation of the γ -lactone by boiling the dihydroxyl-lactam (XI) in mineral acid. It is impossible to close the δ -lactone of the bromolactam by heating in acid. The γ -lactone of the 3,3a-dihydroxyl derivative is also made from the 3-bromo-3a-hydroxyl-lactam (VIII) with sodium hydroxide (X).

Reactions of 2-Oxo-dihydro-3-propionic Acid with Halogen.—Mono-, di- and trihalogen derivatives of 2-oxo-dihydro-indole-3-propionic acid have been described.¹ At that time a tentative formula was given for these compounds.

Further work with this series of compounds has indicated the structures of the two forms of the halogen and hydroxyl derivatives of the hexahydrolactones and lactams, and investigation of the decomposition products of the derivatives of 2-oxo-dihydro-indole-3-propionic acid has resulted in identification of the positions held by the entering halogens and the chemical properties are satisfactorily explained by the following structures. The position first substituted in 2-oxo-dihydro-indole-3-propionic acid is the hydrogen attached to Carbon 3. If two equivalents of iodine are added to the sodium salt of the lactam, all the iodine is found in solution as sodium iodide and crystals may be separated which contain no iodine. This crystalline compound exists in two forms apparently similar to the lactones and lactams described. When treated with hydriodic acid it shows oxidizing power. Since the chemical properties and percentage composition of this substance correspond to the original lactam with the addition of a molecule of water and loss of two atoms of hydrogen, the original structure assigned was an open pyrrolidone ring with a bond between Carbon 7 and the nitrogen (XIV). The neutral form was assigned a lactone structure somewhat similar to the neutral forms of the lactams already described (XV).

Definite evidence for the structure of this compound is furnished by fusion with sodium hydroxide. The original lactam (XIII) heated in an atmosphere of hydrogen with sodium hydroxide to a temperature of 200° can be recovered unchanged. The product obtained after treating the lactam with two equivalents of iodine decomposes under similar conditions and aniline⁴ is volatilized from the fusion flask. This is evidence that Carbon 3 is the point of attack, and the 3-hydroxyl derivative of the original

⁴ Hofmann, *Ann.*, 53, 11 (1845).

lactam is the probable structure of the product obtained after treatment with iodine (XVI). When this compound is heated it loses water and a γ -lactone is formed between the terminal carboxyl and the 3-hydroxyl group with loss of acidic properties (XVII). Such a compound would not add bromine or ozone to a double bond, but could react with hydrobromic acid and could be reduced with hydriodic acid or sodium amalgam.

When the 3-hydroxyl-lactam is treated with methyl sulfate a dimethyl derivative is obtained. One methyl group is attached to the hydroxyl and the second methyl group is presumably attached to the nitrogen, but only one methyl group can be determined with hydriodic acid, as the second methyl group apparently migrates from the nitrogen and is then stable to hydriodic acid.

If the dibromo or di-iodo derivative of this lactam is brominated,¹ the bromine enters a position in which it is exceedingly unstable. This trihalogen compound will lose hydrobromic acid in acetic acid with sodium acetate or in alcoholic solution with cold dil. sodium hydroxide. The resulting product is neutral, and has a percentage composition of a γ -lactone of a dihalogen derivative of the 3-hydroxyl-lactam. The bromine apparently substitutes the hydrogen in Position 3. This is confirmed by the result of alkaline fusion; a volatile oil was obtained which after purification proved to be 2,4-dibromo and 2,4-di-iodo-aniline.⁵

When 2-oxo-dihydro-indole-3-propionic acid is treated with bromine, Position 3 appears to be the primary point of attack; however, it is possible to prepare the 3-hydroxyl-lactam, and the γ -lactone of this compound will form a monobromo substitution product. The only point of interest of this compound is the position occupied by the bromine. Since the compound is easily decomposed with alkali it is difficult to separate sufficient of the monobromo-aniline for purposes of identification; this fact, however, suggests that the bromine occupies position 5 in the indole derivative, and is, therefore, *para* to the amine group. Bromine in the *para* position to the nitrogen is much less stable to alkaline fusion than it is in the *ortho* position. The traces which were separated melted too high for the *o*-bromo-aniline, although it was impossible to purify it sufficiently to obtain a sharp melting point which agreed with the *p*-monobromo-aniline.

The structures of the three halogenated compounds are, therefore, 5-monobromo-, 5,7-dibromo- and 3,5,7-tribromo-2-oxo-dihydro-indole-3-propionic acid.

A remarkable property of this series of compounds is the ease with which the hydrogen of Carbon 3 is oxidized to hydroxyl. In a slightly alkaline solution molecular oxygen will oxidize this lactam and at a *PH* of 7.4, dibromo-indophenol will bring about this oxidation. The details of this

⁵ Ref. 4, p. 47.

reaction have been described elsewhere,⁶ and further investigations of this reaction will be reported in the near future.

Experimental Part

Five determinations have been applied to the compounds described in the Experimental Part. (1) The "direct titration" is the amount of 0.1 *N* sodium hydroxide solution required to neutralize carboxyl groups. This has been determined in alcohol with a 100mg. sample and with phenol-sulfonephthalein as indicator. (2) The "total titration" is the amount of 0.1 *N* sodium hydroxide solution neutralized by 100 mg. of the material after it has been boiled for five minutes with 15 cc. of 0.1 *N* sodium hydroxide solution, and the solution has been back-titrated with 0.1 *N* sulfuric acid. Phenolsulfonephthalein has also been used as indicator in this titration. (3) The "halogen removed" is the halogen in the solution removed by alkali. It has been determined with 0.1 *N* silver nitrate by the method of Volhard. This titration has been made after the solution has been boiled with alkali and acidified with nitric acid. (4) The "cold oxidizing power" is the amount of 0.1 *N* iodine liberated by adding 100 mg. of the compound to a cold solution of 2 g. of potassium iodide and 2 cc. of 1:1 hydrochloric acid contained in 15 cc. of glacial acetic acid. The iodine set free was titrated with 0.1 *N* sodium thiosulfate solution. (5) The "total oxidizing power" is the total amount of iodine liberated by 100 mg. of material. It has been determined by adding the substance to the acetic acid solution of potassium iodide and hydrochloric acid, and then boiling the solution under an inside reflux condenser for five minutes. After the solution has been boiled, it is removed as rapidly as possible from under the reflux and immediately cooled. Water is added until the volume is approximately 100 cc. and the free iodine is determined by 0.1 *N* sodium thiosulfate, with starch as indicator. Unless the solution is cooled rapidly after the refluxing, atmospheric oxygen will liberate iodine. These five determinations will be described as "direct titration" for carboxyl; "total titration" for total acid groups; "halogen removed" for inorganic halogen after boiling with 15 cc. of 0.1 *N* sodium hydroxide; "cold oxidizing power," and "total oxidizing power" for the iodine liberated from hydriodic acid. All melting points are uncorrected.

2-Oxo-3-bromo-3 α -hydroxyl-octahydrobenzofuran-3-propionic Acid (I).—One-twentieth mole (10.5 g.) of 2-oxo-2,3,4,5,6,7-hexahydrobenzofuran-3-propionic acid is dissolved in 200 cc. of hot water and poured into a 500cc. glass-stoppered bottle containing 6 cc. of 9 *N* hydrobromic acid; 2.5 cc. of bromine is added, the bottle tightly stoppered, shaken, placed in a beaker of water on a steam-bath, and heated until no free bromine is present. The solution is concentrated in a vacuum to about 30 cc. The crystals which separate are filtered, thoroughly washed, and dissolved in 50 cc. of alcohol to which 150 cc. of water is added. The solution is allowed to stand for about one hour,

⁶ Kendall, and Ort, *J. Biol. Chem.*, **68**, 611 (1926).

A small amount of the δ -lactone form of the bromolactone may separate. This is filtered off and the solution concentrated in a vacuum. Crystals again separate from the solution, are filtered, washed and dried; yield, about 50%; m. p., 147°.

Anal. Calcd. for $C_{11}H_{13}O_4Br$: C, 42.99; H, 4.92; Br, 26.03. Found: C, 42.71; H, 4.85; Br, 26.00.

Direct titration, 4.8; total titration, 9.9; halogen removed, 3.3 cc.; oxidizing power, 6.4 cc.

To prepare the δ -lactone form, 2.9 g. of the monobromolactone is dissolved in 100 cc. of boiling xylene, which is refluxed for one hour; after standing for several hours crystals separate; yield, 1.9 g. These are treated with 5 cc. of alcohol to dissolve any unchanged material. Thirty cc. of water is then added and the solution filtered. The crystals recrystallized from xylene are identical with the δ -lactone form (II), m. p. 144°, and when mixed with the δ -lactone of the monobromolactone the melting point is unchanged.

δ -Lactone of 2-Oxo-3-bromo-3a-hydroxyl-octohydrobenzofuran-3-propionic Acid (II).—One-tenth mole (20.9 g.) of 2-oxo-2,3,4,5,6,7-hexahydrobenzofuran-3-propionic acid is dissolved in 300 cc. of water containing 20 cc. of 5 *N* sodium hydroxide and 5.3 g. of sodium carbonate. To this is slowly added 5.5 cc. of bromine. The solution is allowed to stand for 18 hours. The crystals which separate are filtered, washed and air dried; yield, 90%; m. p., 144°.

Anal. Calcd. for $C_{11}H_{13}O_4Br$: C, 45.67; H, 4.53; Br, 27.65. Found: C, 45.40; H, 4.46; Br, 27.25.

Direct titration, none; total titration, 10.6 cc.; halogen removed, 3.4 cc.; cold oxidizing power, none; total oxidizing power, 7.0.

2-Oxo-3,3a-dihydroxyl-octohydrobenzofuran-3-propionic Acid (IV).—The γ -lactone of the 3,3a-dihydroxyl-lactone (V) is dissolved in an excess of warm sodium hydroxide solution. The sodium hydroxide is then neutralized with just an equivalent amount of sulfuric acid and the solution is concentrated in a vacuum. After standing for a short time crystals separate; m. p., 164°; direct titration, 4.1 cc.; total titration, 8.6 cc.; oxidizing power, none. If this substance is boiled with 15 cc. of 0.1 *N* sulfuric acid, the solution will back-titrate 15 cc. of 0.1 *N* sodium hydroxide, and the γ -lactone of this derivative can be separated from solution.

γ Lactone of 2-Oxo-3,3a-dihydroxyl-octohydrobenzofuran-3-propionic Acid (V).—One-tenth mole (29 g.) of 3-bromo-3a-hydroxyl-octohydrobenzofuran-3-propionic acid is dissolved in 200 cc. of 1 *N* sodium hydroxide solution and heated to boiling. The solution is made slightly acid with 11 cc. of 10 *N* sulfuric acid and is boiled for 20 minutes. On cooling, crystals of the γ -lactone of the 3,3a-dihydroxyl derivative of the lactone separate. These may be recrystallized from aqueous alcohol; m. p., 146°.

Mol. wt. Subs., 0.2017; in C_6H_5OH , 15.07; Δt , 0.412°. Calcd. for $C_{11}H_{14}O_4$: mol. wt., 226. Found: 246.

Anal. Calcd. for $C_{11}H_{14}O_4$: C, 58.38; H, 6.24. Found: C, 58.34; H, 6.12.

Direct titration, none; total titration, 9.0 cc.; oxidizing power, none.

The γ -lactone of the 3,3a-dihydroxyl-lactone is prepared as follows.

One g. of the 3-bromo, 3a-hydroxyl-lactone is dissolved in a small amount of alcohol, to which 100 cc. of water is added. To this, 4 cc. of 1 *N* sodium hydroxide solution is added and the solution is concentrated in a vacuum. It is allowed to stand for several hours; crystals which separate are removed by filtration. After washing and drying, these crystals are identical with the γ -lactone of the 3,3a-dihydroxyl derivative of the lactone.

2-Oxo-3-bromo-3a-hydroxyl-octohydro-indole-3-propionic Acid (VIII).—One-

twentieth mole (10.5 g.) of the lactam is dissolved in 200 cc. of boiling water. The hot solution is poured into a pressure bottle containing 6 cc. of constant-boiling hydrobromic acid; 2.5 cc. of bromine is added by allowing the bromine to run down the side of the bottle. The stopper is quickly clamped and the contents are well shaken. Most of the bromine disappears in a few minutes and crystals separate as the solution cools. These are filtered, washed and dried; yield, 12 g.; m. p., 156°.

Anal. Calcd. for $C_{11}H_{14}O_4NBr$: C, 43.13; H, 5.27; Br, 26.11. Found: C, 43.12; H, 5.25; Br, 25.90.

Direct titration, 3.4 cc.; total titration, 6.8 cc.; halogen removed, 3.3 cc.; total oxidizing power, 6.5 cc.

It is impossible to make the δ -lactone of the 3-bromolactam by heating this substance in xylene. The solution becomes brown, and the bromolactam rapidly decomposes.

δ -Lactone of 2-Oxo-3-bromo-3a-hydroxyl-octahydro-indole-3-propionic Acid (IX).—One-tenth mole (21 g.) of 2-oxo-2,3,4,5,6,7-hexahydro-indole-3-propionic acid is dissolved in 100 cc. of water by the addition of 20 cc. of 5 *N* sodium hydroxide solution. To this is added 5 cc. of bromine in 100 cc. of 2 *N* sodium hydroxide solution. With agitation, 40 cc. of 5 *N* sulfuric acid is then added. The free bromine which has not reacted is removed in a vacuum and the crystals are filtered off; yield, 17 g.

An alternative method is to dissolve 0.1 mole of the lactam in water containing one equivalent of sodium hydroxide. The solution is made to contain 25% of acetic acid with a volume of about 300 cc. by the addition of acetic acid. By means of an air stream, 5 cc. of bromine is then aerated into the cold solution. Crystals separate in a few minutes; yield, 20 g. These crystals are the δ -lactone of the 3-bromo-3a-hydroxyl-lactam; m. p., 153°.

Anal. Calcd. for $C_{11}H_{14}O_5NBr$: C, 45.83; H, 4.90; Br, 27.76. Found: C, 45.77; H, 4.84; Br, 28.00.

Direct titration, none; total titration, 7.2 cc.; halogen removed, 3.5 cc.; cold oxidizing power, none; total oxidizing power, 7.0 cc.

2-Oxo-3,3a-dihydroxyl-octahydro-indole-3-propionic Acid (XI).—Fourteen g. (0.05 mole) of the 3-monobromo-3a-hydroxyl-lactam (VIII or IX) is dissolved in 40 cc. of 5 *N* sodium hydroxide solution, and the solution is warmed to 60°. After cooling, 42 cc. of 5 *N* sulfuric acid is added and the crystals which separate are filtered off; yield, 7.3 g.; m. p., 180°.

Anal. Calcd. for $C_{11}H_{17}O_6N$: C, 54.29; H, 7.04. Found: C, 54.37; H, 6.89.

Mol. wt. Subs., 0.1500; in C_6H_5OH , 12.66; Δt , 0.42°. Calcd. for $C_{11}H_{18}O_4N$: mol. wt., 225. Found: 213.

γ -Lactone of 2-Oxo-3,3a-dihydroxyl-octahydro-indole-3-propionic Acid (XII).—When the 3,3a-dihydroxyl-lactam is dissolved in boiling dilute mineral acid, the γ -lactone (XII) crystallizes from solution. The compound may be recrystallized from aqueous alcohol; m. p., 206°.

Anal. Calcd. for $C_{11}H_{16}O_5N$: C, 58.64; H, 6.66. Found: C, 57.96; H, 6.58.

Direct titration, none; total titration, 5.2 cc.; total oxidizing power, none.

This compound can be made from the 3-monobromo-3a-hydroxyl-lactam with dil. sodium hydroxide solution. One g. of the 3-monobromolactam is dissolved in a small amount of alcohol and water. To this, 4 cc. of 1 *N* sodium hydroxide is added. The solution is concentrated and allowed to stand. The crystals are filtered, washed and recrystallized from alcohol and water; m. p., 206°. When mixed with the γ -lactone of the 3,3a-dihydroxyl-lactam, the melting point is unchanged.

Formation of Cyclohexadiene Glutaric Acid from 2-Oxo-hexahydrobenzofuran-

3-propionic Acid with Sodium Hydroxide.—Ten g. of 2-oxo-hexahydrobenzofuran-3-propionic acid is heated with 50 cc. of saturated sodium hydroxide solution in a 300cc. Pyrex distilling flask, through which oxygen-free hydrogen is continually passed. The flask is immersed in a Woods' metal bath maintained at 180 to 200°. Water is driven out of the flask, and the contents crystallize to a solid, white mass. This is dissolved in water and when made acid with sulfuric acid crystals separate. These are purified from boiling water; yield, 75%; m. p., 219°; direct titration, 9.3 cc.

Anal. Calcd. for $C_{11}H_{14}O_4$: C, 62.82; H, 6.71. Found: C, 62.30; H, 6.44.

This compound slowly adds two atoms of bromine in acetic acid solution. The bromo addition product easily decomposes with loss of hydrobromic acid.

Formation of trans-Cyclohexane Glycol, Succinic Acid and Valeric Acid from 3,3a-Dihydroxyl-2-oxo-octohydrobenzofuran-3-propionic Acid.—Ten g. of the 3,3a-dihydroxyl derivative of the lactone is dissolved in 15 cc. of water containing a small amount of sodium hydroxide. To this is added 50 cc. of saturated sodium hydroxide solution. The flask is heated in a Woods' metal bath to 200° and oxygen-free hydrogen is passed through the flask. The water which volatilizes from the solution is saturated with potassium carbonate. A small amount of oil separates from the water which is removed and extracted with hot benzene. After evaporating the benzene to small volume, crystals separate; purified by recrystallization from benzene, m. p. 104°.

Anal. Calcd. for $C_8H_{12}O_2$: C, 62.01; H, 10.41. Found: C, 62.03; H, 9.82.

The melting point of the dibenzoyl derivative is 93°. The dibenzoyl derivative of *trans*-cyclohexane glycol prepared from cyclohexane oxide with water melted at 93°. When mixed with the dibenzoyl derivative of the glycol prepared from the alkaline fusion of the hydroxyl-lactone, the melting point was unchanged.

SEPARATION OF SUCCINIC ACID.—The fusion melt in the flask, after the temperature reaches 200°, is dissolved in water and made acid with hydrochloric acid. The solution is evaporated to dryness and the sodium chloride residue and organic material are extracted with ether. The ether is evaporated to dryness and the residue purified by crystallization from water; m. p., 185°.

Neut. equiv. Subs., 0.1000: 16.90 cc. of 0.1 *N* alkali. Calcd. for $C_4H_4O_4$: 16.94 cc.

The *p*-toluide melts at 255°. The boiling point and saponification number of the diethyl ester of this acid agree with those of diethyl succinate.

VALERIC ACID.—When the alkaline fusion of the 3-hydroxyl derivative of the lactone is heated to 300° in an atmosphere of hydrogen a volatile acid passes over with steam after the fusion melt has been acidified with hydrochloric acid. The acid is not easily soluble in water; it separates in oily drops. The aqueous distillate is extracted with ether and the ether is removed by distillation. The residue in the flask is distilled; 0.1100 g. required 10.2 cc. of 0.1 *N* sodium hydroxide, indicating a molecular weight of approximately 100. The acid chloride prepared by means of thionyl chloride may be converted to the acid amide with aqueous ammonia. The acid amide separates from the ammoniacal solution with potassium carbonate and on recrystallization from ether melts at 114°.

Anal. Calcd. for $C_5H_{11}ON$: N, 13.8. Found: 13.6.

Formation of an Indole Derivative, Succinic and Acetic Acids, from 2-Oxo-3,3a-dihydroxyl-octohydro-indole-3-propionic Acid with Sodium Hydroxide.—Sodium hydroxide converts 2-oxo-hexahydro-indole-3-propionic acid quantitatively into 2-keto-cyclohexane-1- α -glutaric acid, which is then changed into cyclohexadiene glutaric acid with alkaline fusion. The 3,3a-dihydroxyl derivative of 2-oxo-hexahydro-indole-3-propionic acid loses only a small amount of its nitrogen as ammonia when fused with sodium hydroxide. Ten g. of the 3,3a-dihydroxyl derivative is heated in the presence

of hydrogen in a 300cc. Pyrex flask, with 50 cc. of saturated sodium hydroxide, after the lactam has been dissolved in 15 cc. of water with a small amount of sodium hydroxide. When the temperature reaches about 170° a volatile oil, which crystallizes, distills with the water. The crystals are separated by extraction with ether and may be crystallized from a mixture of alcohol and water; m. p., 132°.

Anal. Calcd. for $C_8H_{11}N$: C, 79.28; H, 9.16; N, 11.57. Found: C, 79.39; H, 8.80; N, 10.64.

Mol. wt. Subs., 0.1392; in C_6H_5OH , 12.42: Δt , 0.468°. Calcd. for $C_{16}H_{22}N_2$: mol. wt., 242. Found: 182.

This compound in acid solution forms a bromine addition product which is decomposed in boiling water with the liberation of the original material, and bromine does not substitute hydrogen. The positions of the bonds in the molecule were not identified.

Sodium hydroxide separates an amine from the water which distills from the fusion flask. The oil is extracted with ether and if carbon dioxide is passed through the dried ether solution a precipitate is formed. This may be redissolved in water, precipitated with sodium hydroxide and re-extracted with ether. Its chemical properties suggest that it is *o*-aminocyclohexanol.

SUCCINIC ACID.—Succinic acid was separated from the sodium hydroxide fusion in a manner entirely similar to the isolation of this material from the 3-hydroxyl-lactone. It was identified by melting point, carboxyl titration and the toluides.

ACETIC ACID.—From the aqueous solution of the sodium hydroxide fusion a volatile acid is obtained after acidification with hydrochloric acid. Sodium hydroxide is added to the distillate and the solution evaporated to dryness. Sirupy phosphoric acid and ether are added to the beaker and the organic acid extracted with the ether. The ether is removed and the *p*-toluide prepared. Its melting point, 147°, is that of acetic acid toluides.

Fusion of 2-Oxo-dihydro-indole-3-propionic Acid with Sodium Hydroxide.—Ten g. of this lactam is heated in a 300cc. Pyrex distilling flask in an atmosphere of hydrogen with 50 cc. of saturated sodium hydroxide solution, after the material has been dissolved in a few cubic centimeters of water containing sodium carbonate. The atmosphere of hydrogen prevents oxidation of the lactam. The heating is carried out at 200° for one hour. The solution is cooled and water added in the presence of hydrogen. The solution of the fusion mass is made acid with hydrochloric acid. The original lactam precipitates unchanged.

Formation of Aniline from 3-Hydroxyl-2-oxo-dihydro-indole-3-propionic Acid.—When the 3-hydroxyl derivative is fused under similar conditions, a volatile oil is given off at about 210°. The oil is extracted with ether and treated with acetic anhydride. The acetyl derivative is purified by crystallization from hot water; m. p., 114°. The 5,7-dibromo derivative of the 3-hydroxyl-lactam decomposes with sodium hydroxide at 170–180°. The volatile oil is purified by steam distillation, and crystallized from alcohol and water; m. p., 79°; acetyl derivative, m. p. 146°. This agrees with the melting point of 2,4-dibromo-aniline and its acetyl derivative.

Anal. Calcd. for $C_8H_8NBr_2$: Br, 63.70. Found: 63.71.

The 5,7-di-iodo-3-hydroxyl derivative of this lactam, fused with sodium hydroxide, gives an oil which is crystallized from alcohol and water; m. p., 95°. When mixed with 2,4-di-iodo-aniline the melting point was unchanged.

Anal. Calcd. for $C_8H_8NI_2$: I, 73.59. Found: 73.15.

Methylation of 3-Hydroxyl-5,7-dibromo-2-oxo-dihydro-indole-3-propionic Acid.—Seven and two-tenths g. of the γ -lactone of 5,7-dibromo-3-hydroxyl-2-oxo-dihydro-

indole-3-propionic acid is dissolved in 40 cc. of 2 *N* potassium hydroxide solution, and treated with 24 cc. of dimethyl sulfate and 40 cc. of 6.5 *N* sodium hydroxide solution. The dimethyl sulfate and alkali are added alternately in 2cc. portions with vigorous shaking after each addition. Twenty cc. of 10 *N* sodium hydroxide is added and the products are saponified by boiling for 90 minutes. The solution is made acid and the semi-solid precipitate washed a few times in water. This is dissolved in 95% alcohol and diluted to approximately 50% with water. Crystals separate; yield, about 75%; m. p., 140°.

Anal. Calcd. for: $C_{13}H_{13}O_4NBr_2$: C, 38.32; H, 3.21; Br, 39.26. Found: C, 38.31; H, 3.21; Br, 39.00.

Direct titration, 2.5 cc.; total titration, 2.5 cc.; halogen removed, none; oxidizing power, none.

The methyl groups were determined according to the Zeisel micro method.

Anal. Calcd. for $2CH_3$, 7.37; $1CH_3$, 3.65. Found: CH_3 , 3.65.

The ultimate analyses for carbon, hydrogen and bromine indicate the presence of two methyl groups, but as only one can be removed with hydriodic acid it seems probable that the hydroxyl group on Carbon 3 is reduced by the hydriodic acid, and that the methyl attached to the nitrogen then migrates probably to Position 3 and is stable to hydriodic acid under conditions which will remove a methyl group attached to nitrogen.

Summary

2-Oxo-hexahydro-indole-3-propionic acid and its corresponding lactone react with hypobromous acid forming monobromo, monohydroxyl derivatives in which the bromine substitutes the hydrogen in Position 3 and the hydroxyl group is attached to Position 3a. The terminal carboxyl will form a δ -lactone with the hydroxyl group on Carbon 3a.

The bromine in these halogen derivatives can be replaced with hydroxyl by treatment with sodium hydroxide. These dihydroxyl derivatives form γ -lactones between the terminal carboxyl and the hydroxyl group on Carbon 3. They do not form δ -lactones.

2-Oxo-dihydro-indole-3-propionic acid and its mono- and dihalogen derivatives are easily oxidized, resulting in the formation of an hydroxyl group on Carbon 3. The hydroxyl group of these compounds will form a γ -lactone with the terminal carboxyl group.

The positions occupied by the bromine in the mono-, di- and tribromo derivatives of 2-oxo-dihydro-indole-3-propionic acid which have been described in a previous publication¹ have been determined. These halogen derivatives are 5-mono-, 5,7,di- and 3,5,7,-tribromo-2-oxo-dihydro-indole-3-propionic acid, respectively.

KENTUCKY COFFEE NUT TREE SEED OIL¹

BY CHARLES BARKENBUS AND ALEC J. ZIMMERMAN

RECEIVED MAY 17, 1927

PUBLISHED AUGUST 5, 1927

The Kentucky coffee nut tree (*Gymnocladus dioica*) grows over an area extending from central New York westward to Minnesota and southward to the Tennessee line. It is not a common tree and probably grows most abundantly in the State after which it is named. The pods from this tree measure from 8 to 15 cm. in length and have from three to six seeds imbedded in a mucilaginous material. The black seed coating is exceptionally hard and the seed itself is very compact. The average weight of the seeds is about 2.5 g.

The sweet mucilaginous material in the pods is considered by some people to be poisonous, but only brief reports of the poisonous nature could be found in the literature. Cytisine is reported by Chesnut² in the leaves and the mucilaginous material of the pods. A saponin and a toxalbumin are reported to be present in the seeds.³ The same authors report deaths from eating the unroasted seeds but no references are given.

Only very meager reports can be found on the chemical examination of the pods and the seed. Stone and Test⁴ examined the mucilaginous material of the pods for carbohydrates and found glucose and sucrose in large quantities. The insoluble part of the material was provisionally called a gluco-araban. Approximate analysis of the seed and some of the constants of the oil from the seeds has been made.³

Since very little work has been done on the chemical examination of the seeds and the pod, we are subjecting them to a complete examination. This paper deals with the analysis of the oil from the seeds and includes an approximate analysis of the seeds and the pods.

The pods were collected in Fayette County, Kentucky, in the fall of 1923. The seeds were separated from the pods and the pods were air-dried and ground. The seeds were shelled, ground and extracted at once. Most of the work was done one year after collecting but due to an unavoidable delay the results have not been ready for publication.

Experimental Part

Quantitative extractions were made as shown in Table I.

The analysis was made by the official methods. The sugar by inversion is rather high for both the seed and the pod.

Physical and Chemical Examination of the Oil from the Seeds

The oil was obtained by extracting 2360 g. of the shelled, ground seed with absolute ether. The last traces of ether were removed by heating in a vacuum. Four hundred and eighty g. of a clear, light yellow oil with a bland taste was obtained. On standing, the oil deposited a small amount of solid. The oil is practically odorless. The physical and chemical properties are given in Table III.

TABLE III
PHYSICAL AND CHEMICAL CHARACTERISTICS OF THE OIL

d_{20}^{20}	0 9219
n_D^{20}	1.4769
Iodine no. (Hanus)	137.5
Saponification value	191.03
Reichert-Meissl no.	0.44
Acid value	0.39
Acetyl value	11.35
Unsaponifiable matter, %	1.28
Soluble acids (% of butyric acid)	0.83
Insoluble acids, %	93.93 (Iodine no., 132.0)
Unsaturated acids (corr.), %	89.74 (Iodine no., 145.0)
Saturated acids (corr.), %	4.86 (Iodine no., 3.4, before correcting)

The iodine number would indicate a semi-drying oil but only a trace of a film was developed on exposure to the air on a glass plate for a week.

The low Reichert-Meissl number shows that only a trace of glycerides of the lower fatty acids is present, while the low acetyl value indicates a small amount of glycerides of the hydroxylated acids. The oil does not become rancid readily. The saturated and unsaturated acids were obtained by the lead salt-ether method, using the usual precautions and corrections.⁵ The percentage of saturated acids is rather low.

⁵ Baughman, Brauns and Jamieson, *THIS JOURNAL*, **42**, 2398 (1920).

Unsaturated Acids

The bromine addition compounds of the unsaturated acids were made.⁶ No hexabromide was obtained, showing the absence of linolenic acid. The precipitate of the bromides obtained melted at 113–114°. This, with the iodine number, indicates that oleic acid and linolic acid are the two acids present. The percentage composition of the unsaturated acids calculated from the iodine number (145.0) is oleic acid, 39.9%, and linolic acid, 60.1%. These results, calculated to percentage of glycerides in the oil, give 37.41% of oleic acid glyceride and 56.37% of linolic acid glyceride. The molecular weight of the unsaturated acids (280.5) would indicate such a mixture; this was obtained by heating the acids with an excess of alkali and then titrating the excess. The usual method of direct titration gave results much higher (300.5). Repeated attempts to isolate the unsaturated acids under conditions that would eliminate oxidation or polymerization always led to the same results. This has been observed by others.⁷

Saturated Acids

Due to the small amount of saturated acids in the oil (4.86%) we were unable to obtain a quantity large enough to warrant an extended separation by fractional distillation of the methyl esters. The molecular weight by titration was 279.3; m. p. 52–53°. This would indicate that stearic acid was the chief acid present. By repeated fractional crystallization from alcohol a very small top fraction was obtained, melting at 76–77°, showing the presence of arachidic acid. The next fraction melted at 58–60° and had a molecular weight by titration of 275.7. A mixture of 40% palmitic acid and 60% stearic acid would give these results. The lower fractions did not vary much from the second fraction. Although these data are incomplete they do indicate that stearic acid and palmitic acid are the main components of the saturated acids and that arachidic acid is present in small amounts.

Unaponifiable Material

This material which was obtained in small amounts was subjected to an extended fractional crystallization. A very small phytosterol fraction was finally obtained which had a constant melting point of 165–166°.

Anal. Calcd. for $C_{27}H_{46}O$: C, 83.9; H, 11.9. Found: C, 83.47; H, 11.61.

Summary

Approximate analysis of the seeds and pods of the Kentucky coffee nut tree has been made. The physical and chemical characteristics of

SOME PSEUDO-THIOHYDANTOINS AND ALPHA-MERCAPTO ACIDS FROM HIGHER FATTY ACIDS

BY BEN H. NICOLET AND LANGSTON FAIRCHILD BATE¹

RECEIVED MAY 20, 1927

PUBLISHED AUGUST 5, 1927

α -Halogeno derivatives of the simpler fatty acids or their esters condense readily with thio-urea to give 5-substituted pseudo-thiohydantoins. Acids of longer chain than butyric do not seem to have been used for this reaction, and it was thought worth while to extend it to some of the higher homologs, primarily with the hope that the derivatives might be of service in the separation or identification of the higher fatty acids.

Caproic,² lauric, myristic, palmitic and stearic acids were converted by standard methods into the α -bromo acids or esters (these react equally well). When the products, dissolved in five parts of alcohol, were warmed for an hour on the water-bath with slightly more than one molecular equivalent of thio-urea, practically quantitative yields of the crude pseudo-thiohydantoins were obtained. Several crystallizations from alcohol were usually necessary before a constant melting point was reached. The results are summarized in Table I.

TABLE I
PSEUDO-THIOHYDANTOINS

¹ The material here presented is from the Doctor's Dissertation of Langston Fairchild Bate, University of Chicago, August, 1926.

² The work on caproic acid was done by Mr. Sik-Chew Lui.

While the substances obtained are easily formed in excellent yields, they are not at all suitable for the intended use, as they show little or no melting-point depression when mixed, and thus presumably form solid solutions to an unusual extent. A similar product prepared from commercial "stearic acid," containing about equimolecular proportions of palmitic and stearic acids, melted at 175° . It is to be noted that the melting points obtained for the various members of the series are rather close together, and tend to fall as the length of the side chain increases.

As their structure suggests, these pseudo-thiohydantoin can be hydrolyzed to give the corresponding mercapto acids. The method adopted after several trials was to boil a solution of the hydantoin with an equal weight of sodium hydroxide in 10 parts of 85% alcohol. The hydrolysis usually required about 20 hours. At the end of this time, the solution was diluted and acidified, and the acid which separated was decolorized and crystallized from alcohol. The data are summarized in Table II.

TABLE II
 α -MERCAPTO ACIDS

Description	M. p., $^{\circ}\text{C}$.	Formula	Calcd.		Found	
			S, %	Equiv. wt.	S, % ^a	Equiv. wt. ^b
Caproic ^c	b. 234	$\text{C}_6\text{H}_{12}\text{O}_2\text{S}$		148.1		148.2

^a Carius method.

^b By titration in alcohol.

^c The α -mercaptocaproic acid was prepared by hydrolysis with barium hydroxide in much more dilute alcohol and isolated as the barium salt, which was readily soluble in water and melted at 192° .

Anal. Calcd. for $\text{C}_{12}\text{H}_{22}\text{O}_4\text{S}_2\text{Ba}$: Ba, 31.8. Found: 31.74, 31.88.

The relative ease of oxidation of mercaptans to the corresponding disulfides makes it difficult to predict whether products obtained by the procedure described would be the mercapto acids or their oxidation products. The sulfur content and the equivalent weight are scarcely sufficient to decide this question. Accordingly, the substance described as mercapto-lauric acid was dissolved in acetic acid containing sodium acetate in excess, and one equivalent of iodine, also in acetic acid, was added to the warm solution. The iodine was reduced, and from the solution lauric acid α -disulfide was obtained, melting at 48° .

Anal. (Carius). Calcd. for $\text{C}_{14}\text{H}_{28}\text{O}_4\text{S}_2$: S, 13.86. Found: 13.61, 13.55. Equiv. wt. Calcd. (dibasic): 231.3. Found: 233.

The original product was thus evidently the mercapto acid.

A number of the simpler pseudo-thiohydantoins have been oxidized to the corresponding sulfonic acids, usually with potassium chlorate and hydrochloric acid in water solution. This method seemed of doubtful applicability to such insoluble substances as those described in this paper. A number of attempts under rather varied conditions were made to obtain the sulfonic acids in question by oxidation of the mercapto acids, but no products of even approximate purity were isolated except in the case of mercaptocaproic acid.

α -Carboxy-*n*-amylsulfonic Acid.—Barium mercaptocaproate was oxidized in water solution with the calculated amount of barium permanganate. The barium salt of the sulfonic acid was readily soluble in hot water, and melted at 196°.

Anal. Calcd. for $C_6H_{10}O_6S\text{Ba}$: Ba, 41.43. Found: 41.31.

The free sulfonic acid could not be obtained crystalline.

Summary

1. The pseudo-thiohydantoins corresponding to caproic, lauric, myristic, palmitic and stearic acids have been described, together with the α -mercapto acids obtained from them by hydrolysis.

2. The pseudo-thiohydantoins, while easily obtainable, offer no promise as derivatives for the separation or identification of the higher fatty acids.

A SUGGESTED MECHANISM OF THE SPLITTING OF THE CYCLOPROPANE RING BY BROMINE

BY BEN H. NICOLET AND LOUIS SATTLER¹

RECEIVED MAY 20, 1927

PUBLISHED AUGUST 5, 1927

The splitting that occurs when bromine acts on cyclopropane derivatives has usually been considered to take place by the addition of bromine at the bond broken. Cyclopropane carboxylic acid, for example, gives with bromine both the 1-bromo-substitution product and α,γ -dibromobutyric acid. It seems customary to regard these two substances as products of simultaneous and independent reactions.² Bruylants³ remarks that in

¹ The material here presented was used by Louis Sattler in partial satisfaction of the requirements for the degree of Doctor of Philosophy, University of Chicago, 1925.

² After this paper had been prepared for publication, a translation of a rather inaccessible article by Kischner [*J. Russ. Phys.-Chem. Soc.*, **41**, 659 (1909)] was obtained. Kischner remarks: "The described results of the bromination of the chloride of trimethylene carboxylic acid, as well as of the acid itself, may be formulated as the addition of one molecule of bromine. It might be more accurate, however, to describe the production of the end product as the result of two successive stages: (a) the formation of the normal substitution product; (b) the addition of hydrogen bromide, which is accompanied by the rupture of the trimethylene ring." He did not test the action of

this case substitution seems to be "an altogether subordinate reaction."

We have studied the action of bromine on diethyl cyclopropane-1,1-dicarboxylate (I) and found that two products can be isolated, the 2-bromo derivative (II) and β -bromoethyl-bromomalononic ester (III).

When the bromination was carried out at 40–50°, using a powerful quartz-mercury vapor lamp as light source, more II was isolated than when the reaction took place at a higher temperature, with or without illumination. The separation of II and III by fractionation under reduced pressure is tedious, but after four or five distillations moderately pure products were obtained.

The structure of III follows from its reaction with zinc in dil. alcohol; cyclopropane-1,1-dicarboxylic acid was identified. After hydrolysis, III was converted into the phenylhydrazide of α,γ -dihydroxybutyric acid (IV), which was identical with a sample previously obtained in another way.⁴

When II was warmed for nine hours with 80% hydrobromic acid, and the resulting product (presumably α,γ -dibromobutyric acid) hydrolyzed by shaking with silver oxide, the same phenylhydrazide (IV) could be isolated. It was shown to be identical with the other preparations mentioned. It is therefore assumed that hydrogen bromide splits II in such a way as to give III. The formation of IV in this way is evidence for the structure assigned to II, and rules out the alternative possibility that II might be $\text{BrCH}_2\text{CH}_2\text{CH}(\text{CO}_2\text{Et})_2$. This conclusion is confirmed by the fact that the bromine of II is very difficult to remove by hydrolysis.

It is believed that the formation of the dibromide III from the bromo-derivative II has been definitely demonstrated. This result is somewhat surprising, as there was perhaps more reason for expecting the formation of $\text{Br}_2\text{CHCH}_2\text{CH}(\text{CO}_2\text{Et})_2$ in such a reaction. This is, so far as we know, the first case in which the product obtained by the splitting of a bromo-cyclopropane derivative with hydrogen bromide has been determined. The chief interest in the result, however, lies in the identity of the product formed from II and hydrogen bromide with the one to be expected if bromine had added directly to I. The suggestion is obvious that much or all of the III obtained by the action of bromine on I, was formed through II hydrogen bromide on 1-bromocyclopropane-1-carboxylic acid, and assumed such an action as possible only because it involved addition of the bromine (of hydrogen bromide) to the carbon *not* attached to carboxyl.

³ Bruylants, *Bull. soc. chim. Belg.*, **32**, 358 (1923).

⁴ Glattfeld and Sander, *This Journal*, **43**, 2675 (1921). A sample for comparison was kindly supplied by Dr. Glattfeld.

as an intermediate. While it remains possible that III may also be formed directly from I by bromine addition, the evidence for this latter reaction is distinctly less definite. The suggestion is made that the normal action of bromine on the cyclopropane ring may well be not the addition of bromine, but substitution, followed by addition of hydrogen bromide.

There is, of course, no compelling reason why the subsequent addition of hydrogen bromide should always result in the breaking of one of the two bonds adjacent to the carbon carrying the bromine. In fact, Gustavson⁵ found that bromine gave with 1,1-dimethyl cyclopropane, $\text{Me}_2\text{CBrCHBrCH}_3$, a product not derivable by direct bromine addition. He assumed that traces of hydrogen bromide first caused ring splitting to yield Me_2CBrEt , which then underwent bromination to give the observed product, at the same time supplying the hydrogen bromide necessary for the first stage of the reaction. The mechanism he has suggested could not apply to the case discussed in this paper. To settle the question, other monobromo-derivatives of cyclopropane isolated in brominations will have to be heated with hydrogen bromide to see whether the dibromo-compounds obtained are the same as those resulting from "direct" bromination.

The action of bromine on cyclopropylcyanide, 1-cyanocyclopropane-1-carboxylic acid, cyclopropane-1,1-dicarboxylic acid, and ethyl 1-cyanocyclopropane-1-carboxylate is described in the experimental part.

In a further attempt to find reactions in which addition might take place with splitting of the cyclopropane ring, the action of HOCl and HOBr in water solution and that of ICl in glacial acetic acid, were tried on 1-cyanocyclopropane-1-carboxylic acid and on cyclopropane-1,1-dicarboxylic acid. There was no evidence of reaction in any case.

Experimental Part

Preparation of Required Cyclopropane Derivatives.—Ethyl cyclopropane-1,1-dicarboxylate was prepared by the method of Dox and Yoder⁶ with slight modifications. The yield obtained was consistently about 75% of that given by the authors mentioned. The corresponding acid was isolated as described by Stohmann and Kleber.⁷ The yields were decidedly poor. For ethyl 1-cyanocyclopropane-1-carboxylate, the method of Jones and Scott⁸ was used. For 1-cyanocyclopropane, the method of Haller and Benoist⁹ was modified. A 15% excess of potassium hydroxide¹⁰ was pulverized and

⁶ Dox and Yoder, *THIS JOURNAL*, 43, 2097 (1921).

⁷ Stohmann and Kleber, *J. prakt. Chem.*, [2] 45, 477 (1892).

⁸ Jones and Scott, *THIS JOURNAL*, 44, 413 (1922).

⁹ Haller and Benoist, *Ann. chim.*, [9] 17, 28 (1922); little detail is given, but results are surely much less good than the text implies.

¹⁰ Potassium hydroxide was fused for 10 minutes in a silver crucible at about 300°, and poured into warmed test-tubes which were promptly stoppered and placed in a desiccator. This product could be ground effectively as required.

placed in a 100cc. distilling flask fitted with a rather fine capillary and a dropping funnel. The flask was attached to a pump and heated (without fusing the potassium hydroxide) to remove some of the water which had been absorbed during grinding. When the flask had cooled, it was attached, through a condenser and receiver, to the pump, placed in a water-bath at 85°, and γ -chlorobutyronitrile (32 g.) allowed to run in slowly. The reaction should take place rapidly, and the product be removed by distillation as promptly as possible. To obtain a halogen-free product, the distillate was again treated similarly with potassium hydroxide. The yield was 8–11 g. (40–55%) of cyanocyclopropane, boiling at 134°.

Action of Bromine on Ethyl Cyclopropane-1,1-dicarboxylate (I).—Bromine reacts easily with I, even in diffused light. The nature of the product depends on the conditions of bromination. Apparently, both ethyl 2-bromocyclopropane-1,1-dicarboxylate (II) and ethyl β -bromo-ethyl-bromomalonate (III) are formed in each case, but the proportion of the latter was much larger when bromination was carried out at higher temperatures, and with illumination by a mercury arc.

I, preheated to 50°, was treated slowly with 1 mole of bromine in the presence of the arc. The reaction rate increased as hydrobromic acid accumulated and as the solution became warmer. Unless considerable care was taken, the reaction finally became quite violent. On distillation, a typical product (23 g.) gave, in addition to lower-boiling material, (a) 9 g. b_{15} 150–160° and (b) 6 g. b_{15} 160–165°; both fractions consisted chiefly of III.

Anal. Calcd. for $C_6H_{14}O_4Br_2$: C, 31.22; H, 4.07. Found: (a) C, 31.70; H, 4.35. (b) C, 30.91; H, 4.27.

The best sample of III prepared boiled under 10 mm. pressure at 146–151°.

A larger portion of the monobromo derivative (II) was formed when 155 g. of I was placed in a flask attached to a reflux condenser and cooled in an ice-bath while 1 mole of bromine was added during two hours. No special illumination was used. The reaction appeared to be decidedly autocatalytic. After five careful fractionations at pressures of 10–17 mm., II and III were not completely separated.

Anal. Calcd. for $C_6H_{12}O_4Br$: Br, 30.17. Calcd. for $C_6H_{14}O_4Br_2$: Br, 46.20. Found: (a) b_{15} 135–140°; Br, 31.8. (b) b_{15} 140–145°; Br, 32.6, 32.3. (c) b_{10} 146–151°; Br, 45.0.

Formation of Cyclopropane-1,1-dicarboxylic Acid from III. Four g. of an analyzed sample of III was boiled under reflux for five hours with an excess of zinc dust. The solution was then diluted with water, filtered from undissolved zinc, and boiled for some time with excess potassium hydroxide to saponify the ester. From the acidified solution, cyclopropane-1,1-dicarboxylic acid was extracted with ether and recrystallized from chloroform. Three-tenths g. (20%) of the pure acid was obtained. It had the correct melting point, which was not lowered by mixture with a known sample.

Preparation of the Phenylhydrazide of α,γ -Dihydroxybutyric Acid from β -Bromo-ethyl-bromomalonate Ester.—Ten g. of a fraction of the ester III b_{15} 150–155° was refluxed with constant-boiling hydrobromic acid until solution was complete, and the ester presumably converted to α,γ -dibromobutyric acid. Excess hydrobromic acid was removed by distillation at 14 mm. The residue was dissolved in 200 cc. of water, an excess of freshly precipitated silver oxide added, and the mixture shaken for 18 hours in a machine. After filtration, the residue was again shaken with water for some time, and the extract added to the filtrate mentioned. The resulting solutions were concentrated under reduced pressure, the organic material taken up in alcohol, and an excess of phenylhydrazine added. The crystals obtained were purified from ethyl acetate. The yield of pure hydrazide was 1.9 g. (31%); m. p., 129.5°. Mixture with a known sample of the product⁴ did not change the melting point.

Preparation of the Phenylhydrazide of α,γ -Dihydroxybutyric Acid from Diethyl 2-Bromocyclopropane-1,1-dicarboxylate.—Five g. of a fraction b_{11} 135–140° of the ester II, estimated by analysis as 97% pure, was warmed (without boiling) for four hours with 20 g. of 80% hydrobromic acid, and then refluxed for five hours more. After the removal of water and hydrobromic acid by distillation under reduced pressure, the residue, assumed to be α,γ -dibromobutyric acid, boiled at 130–131° under 15 mm. By a procedure similar to that described in the preceding paragraph, this was hydrolyzed with silver oxide, treated with phenylhydrazine, and a phenylhydrazide of α,γ -dihydroxybutyric acid obtained, identical by all tests with that described above.

Action of Bromine on Cyanocyclopropane and on 1-Cyanocyclopropane-1-carboxylic Acid.—After several hours' exposure to the light of a quartz-mercury vapor lamp, almost no bromine had reacted and the products were recovered practically unaltered.

Action of Bromine on Cyclopropane-1,1-dicarboxylic Acid.—Under the influence of ultraviolet light, the action of bromine on this acid is slow, but is completed in three to four hours. In CCl_4 , the product was β -bromo-ethyl-bromomalonic acid,¹¹ of which 2.7 g. (76%) was isolated, melting at 111° and evolving carbon dioxide at 113°. The ammonium salt was precipitated from dry ether.

Anal. (Kjeldahl). Calcd. for $\text{C}_4\text{H}_8\text{O}_4\text{N}_2\text{Br}_2$: N, 8.66. Found: 8.68.

A similar bromination, with chloroform as solvent, took a different course. The product was a very viscous oil. On distillation at 20 mm. it lost carbon dioxide and gave a thick oil, boiling at 140° under 20 mm., which did not solidify at –14°. This was apparently 2-bromocyclopropane-1-carboxylic acid.

Anal. Calcd. for $\text{C}_4\text{H}_5\text{O}_2\text{Br}$: C, 29.09; H, 3.64. Found: C, 29.37; H, 3.57.

Action of Bromine on Ethyl 1-Cyanocyclopropane-1-carboxylate.—This ester behaves with bromine much as does I. Near its boiling point, it reacted vigorously with slowly added bromine and much hydrobromic acid was evolved. Two products, ethyl 2-bromo-1-cyanocyclopropane-1-carboxylate and ethyl α,γ -dibromo- α -cyano-acetate (V), were apparently formed, but a complete separation proved too tedious. After two careful fractionations at 11 mm. pressure, the following analyses were obtained.

Anal. (Carius). Calcd. for $\text{C}_7\text{H}_9\text{O}_2\text{NBr}$: Br, 36.7. Calcd. for $\text{C}_7\text{H}_9\text{O}_2\text{NBr}_2$: Br, 53.7. Found: (a) b_{11} 100–105°, Br, 45.8. (b) b_{11} 136–140°, Br, 52.6.

The latter fraction was apparently moderately pure V.

Action of HOCl and HOBr on Cyclopropane-1,1-dicarboxylic Acid and on 1-Cyanocyclopropane-1-carboxylic Acid.—The acid to be tested was dissolved in alkali and treated with a solution containing 1 mole of NaOCl or NaOBr. The solution was then cooled below 0°, carbon dioxide passed in to liberate the hypohalous acid, and the solution allowed to stand for some time (occasionally up to two days in the ice box). There was no evidence of reaction, and the unaltered acid was recovered in each case.

Action of ICl on Cyclopropane-1,1-dicarboxylic Acid and on 1-Cyanocyclopropane-1,1-carboxylic Acid.—Each acid was treated with 1 mole of ICl in glacial acetic acid solution, and the mixture allowed to stand for periods up to three weeks. There was no evidence of reaction, and titration showed a negligible decrease in the amount of ICl present. Even in ultraviolet light, no reaction could be detected.

Summary

1. Some new derivatives of cyclopropane have been described.
2. In the bromination of diethyl cyclopropane-1,1-dicarboxylate, the 2-bromo-derivative was isolated and shown to react with hydrobromic acid

¹¹ Marburg, *Ann.*, 294, 125 (1897).

to give β -bromo-ethyl-bromomalonic ester. It is suggested that substitution, followed by splitting of the ring with addition of hydrobromic acid, may be the normal mechanism of the breaking of the cyclopropane ring by bromine.

3. A number of cyclopropane derivatives showed no reaction with HOCl, HOBr or ICl.

THE ADDITION OF ETHYL AND TERTIARY BUTYL HYPOCHLORITES TO CINNAMIC ACID

BY ERNEST L. JACKSON AND L. PASIUT

RECEIVED MAY 23, 1927

PUBLISHED AUGUST 5, 1927

The addition of methyl hypochlorite to cinnamic acid and other ethylene derivatives, by the reaction of chlorine with the unsaturated compounds in methyl alcohol solution, was reported in a previous paper.¹ The question of the applicability of this reaction to other alcohols led to the investigation of ethyl and *tert.*-butyl alcohols, the results of which are given in this paper.

Chattaway and Backeberg² have recently shown that in the chlorination of ethyl alcohol, ethyl hypochlorite and hydrogen chloride are the primary products and that in the presence of unchanged alcohol the ethyl hypochlorite quickly eliminates hydrogen chloride from its molecule with the formation of acetaldehyde, the chlorination of which follows. One would expect, therefore, the addition of ethyl hypochlorite to cinnamic acid, by the reaction of chlorine with the unsaturated compound in ethyl alcohol solution, to be complicated by a number of side reactions. The principal reactions follow.

By introducing a slow stream of dry chlorine into an efficiently stirred solution of cinnamic acid in absolute ethyl alcohol, we were able to add ethyl hypochlorite to the double linkage of the unsaturated compound. The chlorine concentration was kept as low as practicable and the temperature was either that of the Laboratory, or 0–10°, the results being about the same in both cases. Most of the chlorine went into the side

¹ Jackson, *THIS JOURNAL*, **48**, 2166 (1926).

² Chattaway and Backeberg, *J. Chem. Soc.*, **125**, 1097 (1924).

reactions, about three times the calculated amount being required to complete the reaction and large quantities of aldehyde being evident in the chlorinated mixture. The products, which were isolated by saponification of the esters resulting from the chlorination, were α -chloro- β -ethoxyphenylpropionic acid, α -chlorocinnamic acid, and α -chloro- β -hydroxyphenylpropionic acid, while the presence of allocinnamic acid was strongly indicated. The yield of the chloro-ethoxy acid was low (about 6%). The α -chloro- β -hydroxyphenylpropionic acid was formed by the addition of hypochlorous acid to cinnamic acid, while α -chlorocinnamic acid was doubtless produced by the action of sodium hydroxide with ethyl α - β -dichloro- β -phenylpropionate during the saponification reaction.³ The reaction of chlorine with an alcoholic solution of ethyl cinnamate was found to give a somewhat higher yield (10%) of the chloro-ethoxy acid.

A number of experiments with alcoholic solutions of cinnamic acid were tried with a view to improving the yield of the chloro-ethoxy acid by eliminating the hydrochloric acid formed in the reaction. Oxidation of the hydrochloric acid by means of potassium chlorate gave a 9% yield of the chloro-ethoxy acid, while 22% of the cinnamic acid was converted into α -chloro- β -hydroxyphenylpropionic acid. Although the yield of the chloro-ethoxy acid was not materially improved by this method, the amount of chlorine required was only one-third that necessary in the absence of potassium chlorate. When calcium carbonate was suspended in the reaction solution, we could isolate only α -chloro- β -hydroxyphenylpropionic acid. With the use of pyridine and the calculated amount of chlorine, 80% of the cinnamic acid was recovered unchanged. On the basis of the equation $C_2H_5ONa + Cl_2 \rightarrow C_2H_5OCl + NaCl$, we tried without success the reaction of the calculated amount of chlorine with a suspension of sodium cinnamate in an absolute alcohol solution of sodium ethylate.

Inasmuch as Goldschmidt⁴ has shown that the addition of ethyl hypochlorite to 1,4-dihydronaphthalene may be accomplished in carbon tetrachloride solution, we hoped to utilize this method for the addition of ethyl hypochlorite to cinnamic acid. It was found, however, that cinnamic acid failed to react with ethyl hypochlorite in carbon tetrachloride, a pure, dry solution of which was prepared by the procedure of Taylor, MacMullin and Gammal,⁵ although tests showed the presence of ethyl hypochlorite in the solution during three days.

The stability of *tert.*-butyl hypochlorite^{5,6} led to the hope that chlorina-

⁶ Chattaway and Backeberg, *J. Chem. Soc.*, **123**, 2999 (1923).

tion of a solution of cinnamic acid in *tert.*-butyl alcohol would result in a more satisfactory addition of the hypochlorite than was obtained in the case of ethyl hypochlorite, where the rate of decomposition apparently exceeds the rate of the addition reaction. We found, in fact, that *tert.*-butyl hypochlorite may be readily added to cinnamic acid in this manner, although only a 14% yield of pure α -chloro- β -*tert.*-butoxy-phenylpropionic acid results. It was necessary to use almost three times the calculated amount of chlorine, because of side reactions between chlorine and *tert.*-butyl alcohol.

(The principal reaction between *tert.*-butyl alcohol and chlorine seems to be substitution of the hydrogen in the methyl groups.⁷ On the basis of the facts at present available, it is not possible to state whether the *tert.*-butyl hypochlorite formed in our reaction is a result of the direct action of chlorine with the alcohol, or is formed by the action of the alcohol with hypochlorous acid, which might result from the reaction of chlorine with small amounts of water present in the alcohol.)

Although the addition of *tert.*-butyl hypochlorite to benzalacetophenone, by its reaction with chlorine and *tert.*-butyl alcohol, could not be established, we were able to isolate a stereo-isomer of α,β -dichloro- β -phenylpropionophenone, which has hitherto not been reported. The new isomer melts at 82–83° and is more soluble in alcohol than the high-melting isomer (113°). That the substance is a stereo-isomer of benzalacetophenone dichloride, and not a structural isomer, was established by its reaction with hydroxylamine to give diphenylisoxazole, which Goldschmidt⁸ has shown to be the product of this reaction with the high-melting dichloride.

The Mode of Addition

In the addition of methyl hypochlorite to cinnamic acid, the chlorine atom has been shown¹ to go exclusively to the carbon atom in the alpha position to the carboxyl group, while the methoxyl radical combines with the carbon in the beta position. This result is analogous to the well-known mode of addition of hypochlorous acid, the methoxyl and hydroxyl groups assuming the same position in the addition product. We found, likewise, that in the addition of ethyl and *tert.*-butyl hypochlorites to cinnamic acid, the chlorine combines with the alpha carbon while the alkoxyl group attaches itself to the beta carbon. Our evidence for the structure of the ethyl and *tert.*-butyl hypochlorite addition products is based upon the preparation of acetophenone by their reaction with alcoholic potassium hydroxide, followed by hydrolysis of the resulting oils with dil. sulfuric acid solution. In the case of the *tert.*-butyl hypochlorite addition product, both acetophenone and α -chloro- β -hydroxyphenyl-

⁷ Davis and Murray, *Ind. Eng. Chem.*, **18**, 845 (1926).

⁸ Goldschmidt, *Ber.*, **28**, 2540 (1895).

propionic acid were obtained by this treatment. The formation of acetophenone and α -chloro- β -hydroxyphenylpropionic acid from the α -chloro- β -alkoxy acid (I) is readily explained as shown by the equations below, while the β -chloro acids (II) would not be expected to yield these products.

Although the unsaturated alkoxy acids resulting from the reaction with alcoholic potassium hydroxide were not isolated, the oils thus obtained were shown to decolorize bromine in carbon tetrachloride solution and to reduce potassium permanganate rapidly in sodium carbonate solution. Perkin⁹ has shown that benzoylacetic acid, on heating with dil. sulfuric acid solution, is quantitatively decomposed into acetophenone and carbon dioxide. One would expect, therefore, our treatment of the product, resulting from the reaction with alcoholic potassium hydroxide, with dil. sulfuric acid solution and steam to yield acetophenone. The formation of α -chloro- β -hydroxyphenylpropionic acid in the reactions with the *tert.*-butyl hypochlorite addition product was doubtless due to hydrolysis of some of the chloro-*tert.*-butyloxy acid.

Experimental Part

Addition of Ethyl Hypochlorite

The ethyl alcohol used in this work was refluxed over quicklime and distilled through a fractionating column. With the exception indicated, the temperature of the experiments was that of the Laboratory.

Reaction of Cinnamic Acid with Chlorine and Absolute Ethyl Alcohol.—Twenty g. of cinnamic acid was dissolved in 100 cc. of absolute ethyl alcohol. A slow stream of chlorine, dried by bubbling through concd. sulfuric acid, was introduced into the vigorously stirred solution. The concentration of chlorine was kept as low as possible, so that several hours were required to complete the reaction. A number of experiments showed that approximately 9 liters of chlorine (about thrice the calculated amount) gave the best results with 20 g. of cinnamic acid. Upon completion of the chlorination the solvent, which had a strong aldehyde odor, was distilled under diminished pressure. The residue was an oil, nearly all of which (20.5 g.) boiled at 122–124° (5 mm.). This material, a mixture of acid esters, was boiled with a small excess of 0.5 *N* sodium hydroxide solution until saponification was complete. The chlorostyrene, formed by the reaction of sodium hydroxide with the dichloride of cinnamic acid, was extracted with ether. Acidification of the alkaline solution precipitated an oil which slowly crystallized. The crystals were filtered off and dried. Recrystallization from benzene gave 2 g. of substance melting at 134–138° and an oil. On further recrystallization of the

⁹ Perkin, *J. Chem. Soc.*, 45, 178 (1884).

substance melting at 134–138° long, transparent needles melting at 137–138° were obtained. The oil crystallized only after long standing. Suction filtration of the sirupy material thus obtained yielded 2 g. of colorless crystals melting at 69–78°, which after several recrystallizations from benzene melted at 78–79°. The oily filtrate from the substance melting at 69–78° was suspended in dil. aqueous sodium hydroxide and boiled until solution was complete and the odor of chlorostyrene was no longer perceptible. Acidification of this solution precipitated an oil, which crystallized on standing; m. p., 57–61°. The substance in dil. sodium carbonate solution rapidly decolorizes aqueous potassium permanganate at room temperature, producing the odor of benzaldehyde. It probably consists chiefly of allocinnamic and isocinnamic acids. In one experiment, by oxidation of this material with potassium permanganate solution and acidification of the resulting solution, there was obtained a small amount of α -chloro- β -hydroxyphenylpropionic acid; m. p., 79–81°. A mixture with the known acid melted at the same temperature.

The crystals melting at 137–138° were shown to be α -chlorocinnamic acid, which was doubtless formed by the reaction of aqueous sodium hydroxide with ethyl α,β -dichloro- β -phenylpropionate during the saponification described above.

Anal. Calcd. for $C_9H_7O_2Cl$: Cl, 19.42. Found: 19.35.

No depression of the melting point was produced on mixing with known α -chlorocinnamic acid; m. p., 137–138°. Also, the melting point of the acid amide, 120–121°, prepared by the procedure of Stoermer,¹⁰ corresponds with that of the acid amide of α -chlorocinnamic acid.

The substance melting at 78–79°, obtained as described above, is α -chloro- β -ethoxyphenylpropionic acid containing one molecule of crystal water. The water of crystallization was determined by heating to constant weight at 115°; the ethoxyl analysis was made by the Zeisel method.

Anal. Calcd. for $C_{11}H_{13}O_3Cl \cdot H_2O$: H_2O , 7.31; OC_2H_5 , 18.26; Cl, 14.37. Found: H_2O , 7.50; OC_2H_5 , 18.26; Cl, 14.21.

By chlorinating a solution of 10 g. of cinnamic acid in 50 cc. of absolute ethyl alcohol cooled in ice water, the yield of the chloro-ethoxy acid was 1 g. (6%).

Structure of the Chloro-ethoxy Acid.—The sample used in the following experiment was shown by an ethoxyl determination to contain 87% of the chloro-ethoxy acid. One and one-half g. of this substance, melting at 77–79°, was added to a solution of 2.4 g. of potassium hydroxide in 13 cc. of absolute alcohol. After boiling under a reflux condenser for six hours, the alcohol was distilled, the residue dissolved in water and acidified, the oil thus precipitated being extracted with ether. To the oil obtained by distillation of the ether there was added 100 cc. of 10% aqueous sulfuric acid; this mixture was then steam distilled until oily material ceased to pass over. From the distillate there was obtained by extraction with ether 0.6 g. of oil which resembled acetophenone in appearance and odor. In order to identify the substance, the semicarbazone was prepared by the reaction of the oil with semicarbazide hydrochloride and sodium acetate according to the usual procedure; m. p., 195–196°; yield, 0.6 g., which corresponds to an amount of acetophenone equal to 65% of the calculated amount, on the basis of a quantitative conversion of the chloro-ethoxy acid into acetophenone. The melting point of the substance showed no depression when mixed with known acetophenone semicarbazone; m. p., 195–196°. From the aqueous solution left in the distilling flask in the steam distillation described above, there was obtained by extraction with ether about 0.1 g. of an oil which was not investigated. Since the formation of acetophenone by these reactions is most logically explained on the assumption that the ethoxyl group is in the

¹⁰ Stoermer, *Ber.*, **44**, 647 (1911).

beta position to the carboxyl group, it is concluded that the substance is α -chloro- β -ethoxyphenylpropionic acid.

Reaction with Ethyl Cinnamate.—A solution of 29 g. of ethyl cinnamate in 100 cc. of absolute ethyl alcohol was treated with 10 l. of chlorine in the manner described above. At the end of the reaction the product was heated with dil. sodium hydroxide solution until saponification of the esters was complete. After extracting the chloro-styrene thus formed, the solution was acidified and an oil precipitated. This on standing partially crystallized. By means of a fractional crystallization from benzene, there were obtained 4 g. of α -chlorocinnamic acid melting at 135–138°, 3 g. of substance melting at 50–105° and 8 g. of oil containing some crystals. By allowing the 8 g. of sirupy material to stand for about three weeks, there were separated with the aid of benzene 4 g. of α -chloro- β -ethoxyphenylpropionic acid melting at 78–80° (10% yield). An ethoxyl determination showed the substance to contain 89% of the chloro-ethoxy acid.

Reaction of Cinnamic Acid with Chlorine and Ethyl Alcohol in the Presence of Calcium Carbonate.—Into a thoroughly stirred suspension of 10 g. of cinnamic acid and 20 g. of finely powdered calcium carbonate in 55 cc. of absolute ethyl alcohol, there was introduced about 4.5 liters of chlorine at such a rate as to maintain only a slight excess. The reaction mixture was then diluted with water and acidified, an oil being precipitated. The oil crystallized on standing; m. p., 60–75°; wt., 7 g. By recrystallization from benzene this material was separated into hydrated α -chloro- β -hydroxyphenylpropionic acid melting at 79–81° (4.5 g.) and 1.5 g. of substance melting at 50–70°, which probably consists chiefly of the low-melting isomers of cinnamic acid. The substance melting at 79–81° is easily soluble in hot water, from which it crystallizes in long needles. A qualitative test by the Zeisel method showed that it contained no ethoxyl group.

Anal. Calcd. for $C_9H_8O_3Cl \cdot H_2O$: Cl, 16.22. Found: 15.61.

Its identity was confirmed by converting it into α -chlorocinnamic acid by reaction with acetic anhydride and sodium acetate,¹¹ and by the preparation of α,β -dichloro- β -phenylpropionic acid by heating it in a sealed tube with fuming hydrochloric acid.

Reaction in the Presence of Potassium Chlorate.—A vigorously stirred suspension of 20 g. of cinnamic acid and 2.6 g. of potassium chlorate in 100 cc. of absolute ethyl alcohol was treated with 3 liters of chlorine (one molecular equivalent) at the rate of about one bubble per second, seven hours being required to complete the reaction. Qualitative tests showed that the solid, suspended in the solution at the end of the reaction, was a mixture of potassium chloride and potassium chlorate. After the chlorination had been completed, the solution was poured into about 1000 cc. of water. The oil, thus precipitated, partially crystallized on standing for about 24 hours. The oily material was separated from the solid by suction filtration. The solid thus obtained weighed 9 g. and melted at 60–77°. By recrystallization from benzene 6.5 g. of hydrated α -chloro- β -hydroxyphenylpropionic acid was obtained; m. p., 79–81°. No depression of the melting point was produced on mixing with the known acid. The oil obtained in the above described filtration was heated with 0.5 *N* sodium hydroxide solution for an hour. After extracting the insoluble material with ether, the solution was acidified, an oil being precipitated. This crystallized on standing for several hours; wt., 6 g.; m. p., 55–63°. This material contains α -chloro- β -ethoxyphenylpropionic acid mixed with the low-melting isomers of cinnamic acid. For purification it was dissolved in dil. sodium carbonate solution and treated with potassium permanganate solution in slight excess. After filtering off the manganese dioxide, extracting the benzaldehyde with ether and acidifying, an oil was precipitated which immediately crystallized. This was filtered off and air dried; wt., 1.8 g.; m. p., 68–75°. A Zeisel test showed the substance

¹¹ Forrer, *Ber.*, 16, 854 (1883).

to be an ethoxyl compound. Recrystallization from benzene gave pure α -chloro- β -ethoxyphenylpropionic acid; m. p., 78–79°. A mixture with the known acid melted at the same temperature. By extracting the filtrate from the substance melting at 68–75° with ether and distillation of the solvent, after drying over sodium sulfate, there was obtained an oil which soon crystallized. From this 1.2 g. of α -chloro- β -ethoxyphenylpropionic acid melting at 65–75° was obtained. One recrystallization from benzene gave the pure chloro-ethoxy acid; m. p., 78–79°.

Addition of Tertiary Butyl Hypochlorite

The *tert.*-butyl alcohol used was the "anhydrous" grade manufactured by the Petroleum Chemical Corporation. The commercial product was found to give about the same results as *tert.*-butanol boiling at 81–82°.

Reaction of Cinnamic Acid with Chlorine and *tert.*-Butyl Alcohol.—A vigorously stirred solution of 25 g. of cinnamic acid in 350 cc. of *tert.*-butyl alcohol was treated with a stream of dry chlorine until approximately 10.5 liters (about 2.8 times the calculated amount) had reacted. The use of less chlorine gave an incomplete reaction of the cinnamic acid because of side reactions between chlorine and *tert.*-butyl alcohol. The temperature was that of the Laboratory, and the rate of introduction of chlorine was such as to maintain only a small excess, about 15 hours being required to complete the reaction. At the end of the reaction the *tert.*-butyl alcohol was distilled under diminished pressure, the bath temperature being 60–70°. The residue was an oil, which was dissolved in ether and thoroughly extracted with saturated aqueous sodium carbonate. The small amount of insoluble material remaining in the ether was not investigated. The sodium carbonate solution was heated at the boiling point for about three minutes. This treatment decomposes cinnamic acid dichloride to give chlorostyrene, which is removed by means of ether. On acidifying the sodium carbonate solution, there precipitated an oil, which was extracted with ether. After drying and distilling the solvent, an oil was obtained. The oil showed slight tendency to crystallize upon standing and with the use of the common solvents, except benzene. It was dissolved in benzene and allowed to evaporate almost to dryness at room temperature. The crystalline mass thus obtained was separated from the oily material by means of suction filtration; m. p., 60–70°. This is principally α -chloro- β -*tert.*-butyloxyphenylpropionic acid contaminated with the low-melting isomers of cinnamic acid. The substance may be obtained completely pure by further recrystallization from benzene; however, the purification may be facilitated by oxidation of the unsaturated compounds with dil. potassium permanganate solution, which was shown to be without action on the chloro-*tert.*-butyloxy acid under the conditions employed. The substance melting at 60–70° was dissolved in dil. aqueous sodium carbonate and to this solution there was added potassium permanganate solution until its color persisted for a few minutes, a large excess being avoided. After filtering off the manganese dioxide thus precipitated, the filtrate was immediately extracted with ether to remove benzaldehyde. Acidification of the sodium carbonate solution gave an oil which readily crystallized. Another crystallization from benzene gave pure α -chloro- β -*tert.*-butyloxyphenylpropionic acid; yield, 6 g., or 14%. The remainder of the material was an oil containing some crystals. The colorless crystals of the chloro-*tert.*-butyloxy acid retain benzene and, on standing, the melting point (83–85°) slowly rises because of the loss of benzene. Before analysis the finely powdered substance was allowed to stand in a vacuum desiccator over phosphorus pentoxide for about a week, when its melting point became constant at 94–94.5°. The benzene may also be removed by crystallization from chloroform.

Anal. Calcd. for $C_{13}H_{17}O_2Cl$: C, 60.80; H, 6.67; Cl, 13.81. Found: C, 60.81; H, 6.68; Cl, 14.15.

Structure of the Chloro-*tert*.-Butyloxy Acid.—To a solution of 5.4 g. of potassium hydroxide in 28 cc. of absolute ethyl alcohol there was added 3.8 g. of the chloro-*tert*.-butyloxy acid melting at 92–94°. After boiling under a reflux condenser for five hours, the alcohol was distilled, the residue dissolved in water and acidified. The oil thus precipitated was extracted with ether; after drying the ether solution and distilling the solvent, 3 g. of red, mobile oil was obtained. Efforts to separate a pure compound from the oil were without success. That it contained an unsaturated compound was indicated by the fact that it decolorized a solution of bromine in carbon tetrachloride, and its sodium carbonate solution rapidly reduced potassium permanganate. The oil was mixed with 100 cc. of 10% sulfuric acid solution and steam distilled until oil ceased to pass over. Extraction of the distillate with ether and distillation of the solvent, after drying, gave 0.9 g. of oil resembling acetophenone in appearance and odor. By treating it with semicarbazide hydrochloride and sodium acetate, acetophenone semicarbazone was obtained; m. p., 195–196°. A mixture of this substance with known acetophenone semicarbazone melted at the same temperature. The identity of the oil was further established by its reaction with hydroxylamine hydrochloride to give acetophenone oxime; m. p., 58–59°.

The aqueous solution remaining in the distilling flask after the steam distillation described above was extracted with ether. From this there was obtained 1.5 g. of reddish oil, which partially crystallized on adding a small amount of water and cooling in ice; wt., 0.3 g.; m. p., 82–84°. After this had been recrystallized from benzene several times and allowed to stand in a vacuum desiccator over phosphorus pentoxide, it melted at 104–105°, which corresponds with the melting point of anhydrous α -chloro- β -hydroxyphenylpropionic acid given by Glaser.¹²

Anal. Calcd. for $C_9H_9O_3Cl$: C, 53.86; H, 4.52; Cl, 17.67. Found: C, 53.89; H, 4.70; Cl, 17.31.

The formation of acetophenone and α -chloro- β -hydroxyphenylpropionic acid by these reactions shows that the alkoxyl group is in the beta position to the carboxyl group, and the substance is α -chloro- β -*tert*.-butyloxyphenylpropionic acid.

Reaction of Benzalacetophenone with Chlorine and *tert*.-Butyl Alcohol.—A solution of 15 g. of benzalacetophenone in 150 cc. of *tert*.-butyl alcohol was treated with 4.5 l. of chlorine in the manner described for cinnamic acid. Distillation of the *tert*.-butyl alcohol gave a colorless oil, which partially crystallized upon standing for several days. After filtering and allowing the filtrate to stand for about four weeks, another crop of crystals was obtained. From the first fraction there was obtained by recrystallization from alcohol 3.5 g. of α,β -dichloro- β -phenylpropiophenone melting at 113–114°. A mixture with the known dichloride of benzalacetophenone melted at the same temperature. The second fraction of crystals obtained as described above weighed 2 g. and melted at 80–90°. A fractional crystallization from alcohol yielded colorless crystals melting at 82–83°. This was found to be a stereo-isomer of α,β -dichloro- β -phenylpropiophenone, which has not hitherto been described.

Anal. Calcd. for $C_{18}H_{15}OCl_2$: C, 64.52; H, 4.33; Cl, 25.41. Found: C, 64.26; H, 3.99; Cl, 25.32.

That the substance is a stereo-isomer of benzalacetophenone dichloride, and not a structural isomer, was shown by its reaction with hydroxylamine to give diphenylisoxazole, which Goldschmidt⁸ showed to be the product of the same reaction with α,β -dichloro- β -phenylpropiophenone melting at 113°. To a solution of 0.35 g. of the low-melting dichloride (82–83°) in 13 cc. of 80% aqueous ethyl alcohol, there was added 0.18 g. of hydroxylamine hydrochloride. After bringing into solution by warming, dil. sodium hydroxide solution was added until tests with litmus showed an excess,

¹² Glaser, *Ann.*, 147, 82 (1868).

Crystals of diphenylisoxazole soon began to separate. After standing for 30 minutes, the solution was filtered and the filtrate was immediately poured into water, which precipitated the diphenylisoxazole; yield, 0.2 g. By recrystallization from alcohol, colorless flakes of the pure substance were obtained; m. p., 140.5–141°. No depression of the melting point was produced on mixing with known diphenylisoxazole (m. p. 140.5–141°), which was prepared by the reaction of hydroxylamine with the dichloride of benzalacetophenone melting at 113–114°.

The principal portion of the material resulting from the reaction of benzalacetophenone with chlorine and *tert.*-butyl alcohol was an oil which did not crystallize after standing for several months and which could not be obtained in the solid state by the use of solvents. In the hope of isolating the *tert.*-butyl hypochlorite addition product, the oil was subjected to a distillation at 5 mm. pressure. This, however, produced deep-seated decomposition, large quantities of gas being evolved. From the fraction boiling at 125–150° ω -chloro-acetophenone was separated; the other products were not identified, although the presence of benzoyl chloride was evident. The ω -chloro-acetophenone, after recrystallization from alcohol, melted at 55–55.5° and possessed the lachrymatory properties characteristic of this substance. Inasmuch as the melting point given in the literature is 58–59°, the crystals melting at 55–55.5° were further identified.

Anal. Calcd. for C_8H_7OCl : C, 62.12; H, 4.57; Cl, 22.93. Found: C, 61.68; H, 4.60; Cl, 23.24.

When treated with hydroxylamine hydrochloride according to the procedure of Korten and Scholl,¹³ it gave synphenylchloromethylketoxime (m. p., 88–89°), a reaction characteristic of ω -chloro-acetophenone.

Summary

1. The reaction of chlorine with a solution of cinnamic acid in absolute ethyl alcohol results in a low yield of α -chloro- β -ethoxyphenylpropionic acid. Oxidation of the hydrochloric acid formed in the reaction by means of potassium chlorate was shown to reduce greatly the amount of chlorine required, although the yield of the chloro-ethoxy acid was not materially improved. A solution of ethyl hypochlorite in carbon tetrachloride was found to be without action on cinnamic acid.

2. The reaction of chlorine with a solution of cinnamic acid in *tert.*-butyl alcohol results in the formation of α -chloro- β -*tert.*-butoxy-phenylpropionic acid.

3. The addition of *tert.*-butyl hypochlorite to benzalacetophenone, by its reaction with chlorine and *tert.*-butyl alcohol, could not be established. However, a new stereo-isomer of α,β -dichloro- β -phenylpropiophenone was isolated.

THE DISSOCIATION INTO FREE RADICALS OF SUBSTITUTED DIXANTHYL

IV. DIXANTHYL AND DIXANTHYL-9,9'-DICARBOXYLIC ACID

BY JAMES B. CONANT AND BENJAMIN S. GARVEY, JR.

RECEIVED MAY 27, 1927

PUBLISHED AUGUST 5, 1927

It has been shown¹ that the aryl and *sec.*-alkyl derivatives of dixanthyl are dissociated in solution at room temperature and that the primary alkyl derivatives dissociate on warming their solutions. The parent substance dixanthyl (I) differs from these derivatives in that no color develops even on boiling its solution in methyl benzoate, and at room temperature it does not combine with oxygen. There is no reason, therefore, to believe that it dissociates into a free radical even at a com-

paratively high temperature.² The carbon-carbon linkage in this compound, however, is very reactive towards certain reagents which bring about cleavage of the molecule.

In dilute carbon disulfide solution bromine reacts with dixanthyl forming two molecules of the perbromide of xanthyl bromide. At room temperature, dixanthyl slowly dissolves in concd. sulfuric acid, yielding a brown solution; on hydrolysis xanthanol is obtained. By analogy with the reaction of acids on dissociated ethanes one would expect xanthane as the other product in this reaction but we were unable to prove its presence in the reaction mixture. The red sodium xanthyl is rapidly formed by shaking an ether solution of dixanthyl with either sodium-potassium alloy or 40% sodium amalgam (a liquid). Tetraphenylethane is similarly cleaved by sodium-potassium alloy³ but not by 40% amalgam. A 2% solution of dixanthyl in dibromobenzene begins to absorb oxygen at an appreciable rate at 150° and at 180–190° the oxidation is complete in five to six hours; the amount of oxygen absorbed corresponds to the for-

¹ Conant and Sloan, *THIS JOURNAL*, **47**, 572 (1925). Conant and Small, *ibid.*, **47**, 3068 (1925). Conant, Small and Sloan, *ibid.*, **48**, 1743 (1926).

² Conant and Sloan [*THIS JOURNAL*, **45**, 2468 (1923)] prepared dixanthyl by reduction of the xanthanol in strong acid solution with vanadous chloride. They believed that the colored precipitate which is first formed might contain the free xanthyl radical in the solid state. We have reinvestigated this point and have failed to obtain any evidence that the pink precipitate contains "free xanthyl." The color seems to be due to small amounts of some highly colored impurity.

³ Ziegler and Thielmann, *Ber.*, **56B**, 1740 (1923).

mation of two molecules of xanthone. The pure compound at 225° absorbs the calculated quantity of oxygen in four to five hours, and xanthone can be isolated from the oxidation product.

All these reactions are characteristic of dissociable ethanes, and when they take place with such a substance as hexaphenylethane, are usually interpreted as reactions of the free radical (for example, triphenylmethyl). With dixanthyl the reactions are slower and either require somewhat more drastic reagents (for example, 40% amalgam instead of 1% amalgam) or a higher temperature, as in the case of the absorption of oxygen. It seems to us highly improbable that these cleavage reactions of dixanthyl proceed through a free radical stage. We seem rather to be dealing with definite reactions of the *single* bond. Even in the case of the oxygen absorption of the colorless solutions of certain dialkyl dixanthyls the reaction may involve a very reactive carbon-to-carbon linkage and not a free radical. In the dixanthyl series we have at our disposal a series of compounds with considerable variations in the reactivity of the single linkage; at the top of the series are those substances like diphenyl-dixanthyl and di-*isopropyl*dixanthyl which dissociate in solution at 25°; at the bottom is the hydrogen compound dixanthyl itself.

It is worth noting that the cleavage of a single bond by halogens, acids, alkali metals and oxygen is strikingly parallel to the action of the same reagents on ethylenic derivatives. The only difference is that in the case of the unsaturated compounds the molecule as a whole stays intact as only one of the two linkages is cleaved. It is very probable, therefore, that the final explanation of the variations in the reactivity of the single bond and the double bond will be found to be closely allied if not identical.

Dixanthyl-9,9'-dicarboxylic Acid and its Ester

In order to compare the dissociating influence of a so-called negative group with that of aryl and alkyl groups, we have synthesized dixanthyl-9,9'-dicarboxylic acid (III) and its dimethyl ester by two methods. Dixanthylene (II) adds two atoms of alkali metal when shaken with sodium-potassium alloy. The resulting compound, on treatment with carbon dioxide, yields the salt of the dibasic acid. The reactions are outlined below; we have written the metallic compound as the potassium com-

pound but have no evidence as to whether sodium or potassium (or perhaps both) is actually involved in the reaction.

The acid may also be obtained by the reduction of 9-bromo-xanthanoic acid with vanadous chloride. The crystalline perbromide was actually employed; it is probably a xanthylum salt and analogous to the salts of the substituted xanthanols, which we have reduced to dixanthyls in an earlier work in this Laboratory. The bromoxanthanoic acid was obtained by bromination of the xanthanoic acid formed by the action of carbon dioxide on potassium xanthyl. This in turn can be prepared by the cleavage of dixanthyl with sodium-potassium alloy or by the action of the same reagent on xanthane. The dimethyl ester of dixanthyl-9,9'-dicarboxylic acid can be prepared by a similar bromination of the methyl ester of xanthanoic acid and subsequent reduction. It may also be prepared by the methylation of the sodium salt of the dibasic acid with dimethyl sulfate.

Dimethyl dixanthyl-9,9'-dicarboxylate reacts rapidly with bromine in carbon disulfide and forms the perbromide of the bromo-xanthanoic ester. It is thus possible to go back and forth from this compound to the dixanthyl di-ester by using either aqueous vanadous chloride or bromine in carbon disulfide.

A solution of dixanthyl-9,9'-dicarboxylic acid in ethyl benzoate in nitrogen becomes red on heating and the color disappears on cooling; this may be repeated a number of times. The first color becomes apparent at about 105°; at 140° a two per cent. solution is light cherry-red. The color darkens on further raising the temperature but above 185° an

irreversible decomposition takes place and the red color disappears. This decomposition is probably some sort of internal oxidation-reduction similar to that observed with the di-alkyl dixanthyls. Xanthanoic acid was isolated from a naphthalene solution of the dibasic acid which had been heated until the red color had appeared and then faded. A solution of the dimethyl ester showed the same reversible color changes on heating but unlike the acid the color showed no signs of fading after ten minutes at 200°; on cooling, the solution became colorless. The first color was visible at 115–120°, and above 175° the solution was cherry-red.

The red color of a solution of the ester or acid in boiling xylene was discharged by the addition of phenylhydrazine. Unfortunately, no crystalline products could be isolated from the reaction mixture. The color also disappeared when oxygen was bubbled through the hot solution. A small quantity of crystalline material was isolated from such an oxidized solution of the ester; analysis showed it to have the composition of the peroxide. The rates of oxygen absorption of the acid and ester were measured in the usual way, using bromobenzene as a solvent at room temperature, and *p*-dibromobenzene at higher temperatures. A solution of the ester at 25° absorbed no appreciable quantity of oxygen in 52 hours but the acid under the same conditions absorbed 9.3% of one mole. At higher temperatures the action is more rapid; carbon dioxide is evolved in the case of the acid and this was absorbed in sodium hydroxide before measuring the change in volume. At 120–130° a dilute solution of the acid reacted with 80% of one mole in six and a half hours. At 150–160°, a similar solution of the ester absorbed 54% in seven hours. A solution of the acid in sodium hydroxide was heated to boiling and oxygen bubbled through for three hours; xanthone was precipitated (about 20%) and on acidification considerable unchanged acid was obtained.

A comparison of the facts stated in the preceding paragraph with the behavior of other dixanthyl derivatives is of interest. The temperature at which dissociation first becomes appreciable, as judged by the appearance of color, is about the same for the ester and acid (115° for the ester, 105° for acid). It is considerably lower than the temperature required for appreciable dissociation of dimethyl-dixanthyl (about 160°) or dibutyl-dixanthyl (about 140°), but greater than that for dibenzyl-dixanthyl (about 80°). On the other hand, towards oxygen the compounds are much less reactive than the least reactive of the dialkyl dixanthyls, all of which in dilute solution absorb one mole of oxygen in less than a day, at 25°.

This marked unreactivity of the compounds towards oxygen is in accord with the only other work that has been done on the effect of negative groups on the dissociation of ethanes. Löwenbein⁴ has prepared the

⁴ Löwenbein, *Ber.*, **58**, 601 (1925).

bislactone of 2,2'-dioxytetraphenyl-succinic acid and has shown by colorimetric measurements that it is considerably dissociated in boiling toluene. The same author later showed that tetra-*p*-anisyl-succinonitrile begins to dissociate at 60–80° and tetraphenyl-succinonitrile at about 140°. The color of Löwenbein's free radicals was discharged by phenylhydrazine but only very slowly by oxygen; a 20% solution of the bislactone in boiling xylene was decolorized by a stream of oxygen in an hour. This rate is of the same order of magnitude as the rates of oxygen absorption by the dixanthyl dibasic acid, but very different, indeed, from those observed with all other dissociable ethanes. Löwenbein has explained this unreactivity of his radicals in terms of a splitting of the free valence between the ethane carbon atom and the oxygen atom of the carbonyl group.

Experimental Part

Reactions of Dixanthyl. (a) *Bromine*.—Five cc. of a 6% solution of bromine in carbon disulfide was added to a solution of 0.2 g. of dixanthyl in 10 cc. of the same solvent. An orange precipitate was formed; after it had been filtered off and washed with petroleum ether it melted with decomposition at 151–153°. A sample of the perbromide of xanthyl bromide was prepared by the action of gaseous bromine and hydrobromic acid on a carbon disulfide solution of xanthanol;⁵ it was identical with the bromide prepared from dixanthyl as shown by color, reactions and mixed melting point.

Anal. For perbromide bromine: Calcd.: 38.0. Found: 38.2.

(b) *Sulfuric Acid*.—A tenth of a gram of dixanthyl was suspended in 30 cc. of concd. sulfuric acid. After 48 hours a brown solution was formed; this was filtered through asbestos, poured onto ice and neutralized. The white precipitate was taken up in ether which was then evaporated. On treating the residue with perchloric acid in dry ether, a yellow precipitate of xanthanol perchlorate (m. p. 218–219°) was obtained. It was identified by a mixed-melting-point determination.

(c) *Cleavage by Alkali Metals*.—A solution of 0.18 g. of dixanthyl in 10 cc. of absolute ether was shaken with 1 cc. of a liquid sodium-potassium alloy (10 parts of potassium and 4 parts of sodium) in dry nitrogen. The solution became red in about a minute and after two and a half hours there was a considerable red precipitate. After treating with carbon dioxide, decomposing the excess of alloy with alcohol and acidifying, 0.12 g. of xanthanoic acid, m. p. 215–217° (see below), was obtained. In a similar experiment with 40% sodium amalgam (a liquid) the solution acquired the characteristic red color of sodium xanthyl, but on working up the product after two and a half hours, only a very small amount of xanthanoic acid was obtained. One per cent. sodium amalgam gave no color even on prolonged shaking.

(d) *Oxygen Absorption*.—A tenth of a gram of dixanthyl dissolved in 9 g. of molten *p*-dibromobenzene absorbed 9.2 cc. of oxygen (N. T. P.) in 6.5 hours; at 148–155° in two other experiments, 2.7 and 2.1 cc. were absorbed in 5.75 and 6.75 hours, respectively. A blank showed that the dibromobenzene itself absorbed no oxygen under similar conditions. To oxidize 0.1 g. of dixanthyl to xanthone requires 9.3 cc. of oxygen (N. T. P.). A tenth of a gram of dixanthyl without any solvent absorbed the calculated quantity of oxygen in from 3 to 4.5 hours; xanthone was isolated and identified by mixed-melting-point determination. The apparatus used in measuring the rate of oxygen

⁵ Gomberg and Cone, *Ann.*, **376**, 193 (1910).

absorption at elevated temperatures consisted of a bulb of about 20 cc. capacity heated in a paraffin bath and connected to a gas buret having mercury as the containing liquid.

(a) **Preparation from Dixanthyl.**—In a typical run for the preparation of this acid, 2.25 g. of dixanthyl in 150 cc. of dry ether was shaken overnight with 10 cc. of sodium-potassium alloy under nitrogen in a 500 cc. glass-stoppered distilling flask with the side arm sealed off. The solution was then brick red and there was a brick-red precipitate. The flask was then cooled in a bath of ice and salt and dry carbon dioxide was passed in by breaking off the tip of the side arm. Common ether was then added and the contents of the flask were washed into a beaker. The moisture in the ether caused the alloy to coagulate so that it could easily be removed by a small glass dipper. Water was then added to dissolve the sodium salt, and the ether and water layers were separated. The alkaline water layer was acidified. This threw out a copious, very finely divided precipitate which was extracted with ether. The ether was dried over calcium chloride and evaporated. The residue was recrystallized from 50% ethyl alcohol. The product crystallized in long, white needles which softened slightly at 222° and melted at 223–224°. The yield of recrystallized product was 1.6 g.

(b) **Preparation of Xanthanoic Acid from Xanthane.**—In the preparation of the acid 0.3 g. of xanthane in 15 cc. of dry ether was shaken for ten minutes with 5 cc. of sodium-potassium alloy. The solution was brick red and there was some brick-red precipitate. This sodium xanthyl was treated with carbon dioxide, as in the previous case. A small amount of acid was obtained which was recrystallized from 50% ethyl alcohol and then from ether and petroleum ether; m. p., 218–219°. When mixed with some of the acid obtained from dixanthyl (m. p. 222–223°) the mixed melting point was 221–222°.

Anal. Calcd. for $\text{C}_{14}\text{H}_{10}\text{O}_5$: C, 74.3; H, 4.4. Found: C, 74.7; H, 4.6. Equiv. wt. by titration in 50% alcohol with standard sodium hydroxide solution (phenolphthalein indicator). Calcd. for $\text{C}_{14}\text{H}_{10}\text{O}_5$: 226. Found: 220, 226.

On heating to 290–300°, xanthanoic acid decomposes, giving carbon dioxide and xanthane. Bromination in carbon disulfide produced a dark red precipitate (m. p., 162–163°) and evolution of hydrobromic acid. The red precipitate on reduction with vanadous chloride in concd. hydrochloric acid yielded dixanthyl-9,9'-dicarboxylic acid (see below).

Xanthanoic acid may be converted into its methyl ester by methylation of the sodium salt with dimethyl sulfate at 100° or by the action of thionyl chloride and absolute methyl alcohol. The ester can be recrystallized from methyl alcohol; it melts at 85–86°.

Perbromide of Methyl-9-Bromo-xanthanoate.

Bromination of the methyl ester in carbon disulfide yielded a red precipitate with

evolution of hydrogen bromide. It was purified by washing with petroleum ether; it melted at 158–159° with decomposition.

Anal. for perbromide bromine. Calcd. for $C_{18}H_{18}O_4Br$: Br, 33.4. Found: 33.5.

Preparation from Dixanthylene.—In a typical run 2.4 g. of dixanthylene, 350 cc. of dry ether and 15 cc. of sodium-potassium alloy under dry nitrogen, were shaken for 12 hours in a glass-stoppered distilling flask with the side arm sealed off. The solution was a deep reddish-purple and there was a dark precipitate. The flask was cooled in an ice-and-salt bath and carbon dioxide was introduced by breaking the tip off the side arm. Considerable white precipitate formed. The contents of the flask were washed into a beaker with common ether. The moisture caused the alloy to coagulate and it was removed with a small, glass dipper. Water was added and the mixture shaken. The two layers were then separated. The ether was sucked out of the water layer, which was turbid. The water layer was filtered four times before a clear, yellow solution was obtained. When this solution was then acidified considerable precipitate formed which quickly coagulated and was filtered off, washed well and dried. It commenced to darken at 125° and decomposed up to 155°.

Numerous attempts to purify the acid by crystallization from various solvents failed; the only way to purify the material was to dissolve in aqueous alkali, filter and reprecipitate with acid. When the acid which had been precipitated from a clear alkaline solution was redissolved after standing, there was usually a small residue of xanthone. The clear alkaline solutions slowly deposited small amounts of the same material, evidently due to oxidation by the air.

Anal. Calcd. for $C_{28}H_{18}O_6$: C, 74.7; H, 4.0. Found: C, 74.5; H, 4.3.

Equiv. wt. by titration (phenolphthalein indicator). Calcd. for $\frac{1}{2} C_{28}H_{18}O_6$: 225. Found: 221, 230.

Oxidation with Oxygen.—Half a gram of the acid was dissolved in 15 cc. of 5% sodium hydroxide, the solution diluted to 30 cc. and heated to boiling for three hours under a return condenser while a current of oxygen was bubbled through. After cooling and standing overnight, 0.075 g. of xanthone was filtered off. On acidification considerable dixanthyl-9,9'-dicarboxylic acid was obtained, somewhat pink in color. It melted, with decomposition, at 110–150° and was further identified by analysis. (Found: C, 74.0; H, 4.3.)

When the acid was dissolved in *p*-dibromobenzene and heated in oxygen at 150–160° there was no change in volume after seven hours. However, when the apparatus was disconnected and the bulb submerged in concd. potassium hydroxide, 6 cc. was drawn into the bulb, showing that carbon dioxide was formed. For further experimentation a tube filled with slightly moist potassium hydroxide was inserted between the reaction bulb and the gasometer. With this apparatus a solution of 0.15 g. of the acid in 7 g. of dibromobenzene absorbed oxygen as follows: at 120–130°, 80% of one mole in 6.5 hours and 100% in 13 hours.

The rate of oxidation by oxygen in bromobenzene at 25° was determined in the usual manner. Only 9.3% of one mole was absorbed in three days.

Color on Heating.—A solution of 0.225 g. of the acid in 10 cc. of ethyl benzoate was heated in an atmosphere of nitrogen. The temperature was fixed by plunging the tube in a hot paraffin bath. At 90° there was no color; at 105° the first color became

apparent, which faded on cooling. This was repeated. At 150° the color became a light cherry-red; this faded on cooling, but the solution remained somewhat more colored than it was originally. At 180–200° the red color faded to yellow in about five minutes.

A sample of 0.2 g. of the acid was mixed with 10 g. of naphthalene and heated in a paraffin bath under nitrogen until the color faded. When cold, the tube was broken. The contents were dissolved in ether and this solution was extracted with sodium carbonate. Both the ether and the alkaline layers were yellow. The precipitate formed by the acidification of the alkali layer did not coagulate and was, therefore, extracted with ether, which was dried and evaporated. A yellow oil and a few crystals were obtained. This product was taken up in hot 50% ethyl alcohol and the solution filtered from a few crystals which melted above 240° and were not identified. When cold, the solution was filtered but no product was obtained. It was then extracted with ether which was dried and evaporated. Gummy crystals were obtained. They were washed in 50% ethyl alcohol. In this way a small quantity of crystals of xanthanoic acid was obtained (m. p. 218–220°) and identified by a mixed-melting-point determination.

When a solution of the acid in xylene was heated almost to boiling, the reddish color of the radical was quite apparent. When a solution of phenylhydrazine in xylene was added to this hot solution the radical color faded at once. No precipitate was formed. Several attempts to isolate xanthanoic acid from this reaction mixture failed, the only product being a yellow oil.

The dibasic acid was converted to its dimethyl ester by boiling a solution of it in 5% sodium hydroxide with dimethyl sulfate, the gummy precipitate being filtered from the still strongly alkaline solution. It was also prepared by the reduction of the perbromide of bromo-xanthanoic ester as follows. A solution of 0.5 g. of the perbromide in 125 cc. of concd. hydrochloric acid was treated with 3 cc. of 0.5 *N* vanadous chloride. A pinkish precipitate was formed. It was dissolved in ether, the solution extracted with aqueous sodium hydroxide, the ether solution then dried and the ether evaporated. A flaky, amorphous solid was left, melting over the range 90–110°. The ester could not be crystallized from any solvent that was found. On evaporating a dry ether solution it was obtained as an amorphous, flaky solid; an alcoholic solution evaporated in a vacuum left a yellow gum which hardened to a pliable solid. A similar solid could be obtained by precipitation with water from methyl alcohol. All samples melted indefinitely between 85 and 110°, but could be dried in a vacuum for analysis and molecular-weight determination.

Anal. Calcd. for $C_{30}H_{22}O_8$: C, 75.3; H, 4.6. Found: C, 75.2; H, 4.9.

Mol. wt. in freezing benzene. Subs., 0.2708 g., 0.5876 g. Solvent, 17.37 g.; Δt , = 0.208°, 0.419°. *Mol. wt.* Calcd.: 478. Found: 393, 414.

A solution of the ester in ethyl benzoate (0.24 g. in 10 cc.) heated in nitrogen showed a faint color at 115°; at 125° the color was deeper and faded on cooling. This could be repeated many times. Above 125° the color deepened, being cherry-red at 170°. It did not fade on keeping at 200° for ten minutes, but faded on cooling; on again heating to 200° the cherry-red color deepened as before. These experiments were performed both with the material prepared by esterification of the dibasic acid and by reduction of the perbromide; the reversible appearance of color was the same with both samples,

A solution of the ester in carbon disulfide (0.14 g. in 8 cc.) when treated with bromine gave a red precipitate *without* evolution of hydrogen bromide. This precipitate was shown to be the perbromide of methyl bromo-xanthanoate by mixed melting point (158–159°) and by analysis.

Oxygen Absorption.—When 0.14 g. of the dimethyl ester was dissolved in 10 cc. of bromobenzene in the usual oxygen-absorption apparatus, there was no absorption in 52 hours.

The oxygen absorption at high temperatures was determined in the same apparatus which was used for the acid, using 0.14 g. of the ester and 7 g. of *p*-dibromobenzene. The absorption at 120–130° was 36.4% of one mole in seven hours. At 150–160° it was 53.4% of one mole in seven hours and 87.7% of one mole in 11 hours.

Two samples of 0.1 g. of the dimethyl ester were dissolved in 5 cc. of xylene in test-tubes under nitrogen and the solutions heated to boiling. The color deepened to a decided red tint. A stream of nitrogen was passed into the first, just above the surface of the liquid. The color remained in this solution for 35 minutes and then faded on cooling. Fifteen minutes later the color again deepened when the solution was heated, and faded on cooling. Ten minutes later this was again repeated. A stream of oxygen was bubbled through the second tube while the xylene was boiling. The red color faded in about five minutes and there was no further change on subsequent heating and cooling. The xylene was steam distilled from the second solution, leaving a yellow oil. Attempts to crystallize this oil from methyl alcohol yielded a small quantity of white crystals, m. p. 176°, with gas evolution. Further small quantities of this product were obtained in subsequent, similar runs.

Anal. Subs., 0.01137: CO₂, 0.02922; H₂O, 0.00426. Calcd. for C₂₀H₂₂O₄: C, 70.6; H, 4.3. Found: C, 70.1; H, 4.2.

A red solution of the ester in boiling xylene was treated with phenylhydrazine in nitrogen. After seven minutes at the boiling point, the color had faded and no more color was developed on subsequent heating and cooling. No crystalline products could be isolated from the reaction mixture.

Summary

1. The following cleavage reactions of dixanthyl have been demonstrated: (a) with bromine in dilute carbon disulfide; (b) with sodium-potassium alloy and 40% sodium amalgam; (c) with concd. sulfuric acid; (d) oxidation by oxygen above 150°. There is a striking parallel between these reactions of the single carbon bond and addition reactions of ethylenic compounds.

2. Dixanthyl-9,9'-dicarboxylic acid and its dimethyl ester have been synthesized by two methods. Solutions of these compounds, when heated above 100°, show reversible color changes characteristic of dissociable ethanes. Judged by the temperature required for appearance of radical color, the carboxy and carbomethoxyl groups have a slightly greater dissociating influence than primary alkyl groups. In spite of this, the compounds are only very slowly oxidized by oxygen even above 100°.

THE MECHANISM OF THE WURTZ-FITTIG REACTION¹

By W. E. BACHMANN AND H. T. CLARKE

RECEIVED MAY 31, 1927

PUBLISHED AUGUST 5, 1927

In a search for a convenient laboratory method for the preparation of relatively large quantities of biphenyl, one of us with T. F. Murray, some three years ago, investigated the action of sodium on chlorobenzene at the boiling temperature. It was found that while biphenyl was produced in about 20% of the calculated yield, it was accompanied not only by a high proportion of benzene, but the residue, on distillation with steam, yielded a hydrocarbon of higher boiling point, which melted at 57° and was apparently identical with the hydrocarbon melting at 57–58° isolated by Weiler² from the products of the action of sodium upon bromobenzene. Analysis and molecular-weight determination of this compound show it to be a diphenylbenzene; since the *meta* and *para* isomers are well known, the new compound must be the *ortho* derivative. This has been confirmed by synthesis.

We have also been able to isolate two other hydrocarbons of high molecular weight, which are not volatile with steam; these are triphenylene, which was isolated (although not identified) by Schultz³ from the products of the action of sodium upon bromobenzene according to the directions of Fittig,⁴ and a hydrocarbon, C₂₄H₁₈, which we have proved by synthesis to be *o,o'*-diphenylbiphenyl. All three of these hydrocarbons were isolated by Weiler who, however, made no attempt to characterize them beyond determining their molecular weight.

Two other products, melting at 167–168° and 151–152°, respectively, were described by Weiler, but we have been unable to detect either of them among the products of the action of sodium upon chlorobenzene. On the other hand, like Weiler, we have isolated very small amounts of *p*-diphenylbenzene from among the products of our reaction.

A considerable quantity of a sirupy hydrocarbon is also formed; analysis shows it to consist of hydrocarbons of approximately the same empirical composition and molecular weight as the above products, but we have no clue as to their constitution.

The mechanism of the Wurtz-Fittig reaction has received ample discussion, particularly in the recent papers of Schlubach and Goes⁵ and Goldschmidt and Schön.⁶ The alternative theories advanced in

¹ Reported before the Organic Division, American Chemical Society, at Richmond, Virginia, April, 1927.

these papers, involving on the one hand the formation of free radicals, and on the other the reaction between sodium aryls⁷ and halogen compounds, are equally capable of interpreting the formation of benzene⁸ and biphenyl.

Now Schorigin⁹ has demonstrated that metallic alkyls can exchange their metal for hydrogen when treated with aromatic hydrocarbons, and we have been able to show that an analogous migration of sodium takes place in the sodium aryls.

A suspension of mercury di-*p*-tolyl was converted into the corresponding sodium derivative by the action of metallic sodium in the presence of benzene; by the action of carbon dioxide there were formed not only *p*-toluic acid but also benzoic and phenylacetic acids, indicating the partial migration of sodium (either simultaneously with the replacement of the mercury or subsequently thereto) from the *para* carbon atom of the toluene to the side chain and to the benzene in which the mixture was suspended.

By assuming the transference of sodium from sodium phenyl to biphenyl, an explanation of the formation of diphenylbenzene is readily forthcoming.

The diphenylbiphenyl may be regarded as being formed in an analogous manner from diphenylbenzene.

On the other hand, this type of mechanism cannot be made to account for the formation of triphenylene, and we regard the presence of this compound among the reaction products as decisive in favor of the free radical explanation. This involves the interaction of two free phenyl radicals to form benzene and free phenylene, $2 \text{C}_6\text{H}_5\cdot = \text{C}_6\text{H}_6 + \text{C}_6\text{H}_4\cdot$, which condenser either with itself, to form triphenylene

or with phenyl, to form diphenylbenzene and diphenylbiphenyl.

We are, however, far from suggesting that sodium aryls play no part in the Fittig reaction, for it has been shown by Schlenk¹⁰ that free aryls and alkali metals can unite to form metallic aryls.

¹⁰ Schlenk, *Ber.*, **49**, 608 (1916).

In the hope of throwing more light on the problem, the reaction between sodium and chlorobenzene was carried out in the presence of an excess of toluene, with the idea that this latter hydrocarbon might act as a hydrogen donor and thus appear among the products of reaction.

This was found to be the case; the formation of biphenyl was apparently entirely suppressed, and the fraction which should have contained it consisted of a mixture of *p*-methylbiphenyl and diphenylmethane. The yield of benzene rose to 34% in the case when the sodium was added to the mixture of chlorobenzene and toluene and to 46.5% when the chlorobenzene was added to the sodium suspended in the toluene.

This participation of the toluene in the reaction recalls the observation of Schorigin¹¹ on the action of sodium upon mixtures of mercury diethyl and benzene, toluene, etc., in the presence of carbon dioxide, whereby benzoic acid, phenylacetic acid, etc., are formed. It also finds an analogy in the experiment above quoted in which we have obtained benzoic and phenylacetic acids by treating mercury di-*p*-tolyl successively with sodium and carbon dioxide in the presence of benzene.

Similarly, when chlorobenzene is added to a suspension of sodium in hot dimethylaniline, the latter compound acts as a donor of hydrogen; 49% of the chlorobenzene is recovered as benzene, biphenyl is formed in only minute amounts, and the pitch-like residue contains nitrogen. This pitch, the nature of which was not closely investigated, is insoluble in dil. hydrochloric acid, and appears to contain compounds related to diphenylamine, since its solution in acetic acid readily develops a blue color on exposure to air. Basic compounds are also formed in small (about 2%) amounts; no systematic attempt was made to separate them but derivatives of benzyraniline appear to be present, as is indicated by the formation of benzaldehyde on oxidation in acid solution.

The fact that the yield of benzene appears never to exceed 50% of that theoretically obtainable from the chlorobenzene in the presence of a hydrogen donor, leads us to advance the tentative hypothesis that the free phenyl radical can exist in two electromeric forms, of which only one is capable of accepting hydrogen under the given conditions. The formation of these types of opposite polarity could be explained by postulating their formation by the interaction of chlorobenzene and sodium phenyl.

It is noteworthy that no *o*-diphenylbenzene could be detected in the residues from about 5 kg. of pyrogenic biphenyl, which yields relatively large quantities of *m*- and *p*-diphenylbenzene and a small amount of triphenylene.¹² The hypothesis that this last compound is formed by the dehydrogenation of any *o*-diphenylbenzene initially produced was disproved by passing the latter substance through a red-hot tube, in an atmosphere of carbon dioxide, when only biphenyl and a little carbon were found together with unchanged *o*-diphenylbenzene.

¹² Compare Schmidt and Schultz, *Ann.*, **203**, 135 (1880). Mannich, *Ber.*, **40**, 164 (1907).

The Wurtz synthesis of aliphatic hydrocarbons appears to proceed along analogous lines. When *n*-heptyl bromide is treated at the boiling temperature with sodium, the following products are formed: heptane, 9%; heptylene, 3%; tetradecane, 67%; heneicosane, 3%, as well as hydrocarbons of higher molecular weight. A qualitative experiment with *iso*-amyl bromide and sodium yielded a pentadecane analogous to the above heneicosane.

Michael,¹³ who noted the formation of alkylene and the paraffin corresponding to it, considered that hydriodic acid was first eliminated and that the nascent hydrogen, resulting from the action of sodium upon it, converted a part of the alkylene into paraffin. This explanation takes no account of the formation of products of high molecular weight, and we believe that the facts can be more satisfactorily explained by the assumption of free radicals.

The formation of alkylene¹⁴ is represented as being preceded by that of free alkylidene, part of which reacts with free alkyl to form the triple compound. The chain of reasoning in this instance is incomplete, owing to the difficulty in determining the constitution of the heneicosane, which should, according to the above hypothesis, possess the structure

Analogous reactions have been observed among the alkyl magnesium halides. Späth¹⁵ showed that when the alkyl group contains two or more carbon atoms, the action of alkyl halides on alkyl-magnesium halides consists not only in the direct union of the participating alkyl groups but also in the formation of alkylene and the corresponding paraffin, while Fuson,¹⁶ in a recent study of the action of benzyl chloride upon methyl-magnesium iodide, noted as the principal reaction the formation of equivalent quantities of dibenzyl and ethane, with the formation of ethylbenzene as a side reaction. Both of the above cases can be readily explained by assuming the intermediate formation of free radicals.

¹³ Michael, *Am. Chem. J.*, **25**, 429 (1901).

¹⁴ It is noteworthy that the action of sodium upon bromocyclopentane leads to very poor yields of dicyclopentyl and much cyclopentene [Zelinsky, Titz and Fatejew, *Ber.*, **59**, 2580 (1926)]. The formation of cyclopentane is not recorded.

Experimental Part

Action of Sodium on Chlorobenzene.—Five kg. (44.4 moles) of chlorobenzene was heated in a 12-liter Pyrex flask, provided with an efficient stirrer and a reflux condenser, the inner tube of which was constructed of brass tubing of 15–20 mm. internal diameter. When boiling began the flame was extinguished and 460 g. (20 g. atoms) of sodium was added, piece by piece, through the condenser, at such a rate that the mixture boiled as rapidly as possible without loss of vapor. Vigorous stirring was maintained throughout the addition, which required four to five hours. When all had been added, the rather pasty mixture was allowed to cool somewhat and subjected to steam distillation until all of the unchanged chlorobenzene had been driven over. The distillate was separated and the oil carefully fractionated through a bubbler column¹⁷ when the following fractions were obtained: up to 83°, 407 cc.; 83–95°, 14 cc.; 95–110°, 8 cc.; 110–125°, 26 cc.; 125–130°, 28 cc.; from which the total amount of benzene was estimated at 427 cc. or 375 g., corresponding to 4.8 moles or 24%. The balance of the chlorobenzene was distilled through the column, and the small amount of residue containing biphenyl was joined to the dark, tarry residue from the steam distillation.

This was separated from the solution of sodium chloride and distilled under 15 mm. pressure through a short fractionating column. The following fractions were collected: up to 126°, 14 g.; 126–130°, 330 g.; 130–150°, 20 g.; 150–175°, 25 g.; 175–190°, 14 g.; 190–200°, 176 g.; 220–225°, 33 g.; 225–250°, 62 g.; residue, 350 g. Fraction 126–130° (15 mm.) consisted of almost pure biphenyl. Chlorine could not be detected in any of the fractions distilling above 130° (15 mm.).

***o*-Diphenylbenzene.**—The fraction 190–200° (15 mm.), on cooling, solidified to a mass of long, heavy needles, the setting-point being 50–51°. On recrystallizing from methyl alcohol, large, colorless monoclinic prisms were obtained which melted at 57°; the mother liquor, on evaporation at ordinary temperature, yielded a further crop of the same crystals contaminated with a little oily impurity. Further recrystallization did not raise the melting point above 57°. The compound boils under atmospheric pressure at 332° (corr.). It is somewhat soluble in cold methyl alcohol, and extremely readily in acetone and in chloroform.

Mol. Wt. Ebullioscopic method of Menzies and Wright;¹⁸ solvent, benzene. Solvent, 25.296. Subs., 0.2473, 0.5807, 0.9191; Δt , 0.1084°, 0.2546°, 0.4021°. Calcd.: 230. Found: 235, 235, 236.

By oxidation of 5 g. of *o*-diphenylbenzene with chromic acid in acetic acid, according to the method employed by Kuhn and Winterstein¹⁹ for the oxidation of *p*-diphenylbenzene, there was obtained 0.2 g. of an acid which after recrystallization from petroleum ether melted at 108–110° and showed no change in melting point on mixing with *o*-phenylbenzoic acid prepared from fluorenone. When heated with phosphorus pentachloride it yielded yellow crystals of fluorenone. The corrected melting points and boiling points of the isomeric diphenylbenzenes were determined under the same conditions.

¹⁸ Menzies and Wright, *This Journal*, **43**, 2314 (1921).

¹⁹ Kuhn and Winterstein, *Ber.*, **60**, 434 (1927).

***p*-Diphenylbenzene.**—The fraction boiling at 200–225° (15 mm.) partially solidified on long standing. The solids were separated by moistening the mass with acetone and filtering. On recrystallization from acetone there was obtained a small quantity of leaflets which on recrystallization from a mixture of chloroform and acetone melted at 210° (corr.) and were identical with *p*-diphenylbenzene obtained by the action of a hot wire on benzene. The total amount obtained was 0.15 g.

The mother liquor from the *p*-diphenylbenzene yielded about 3 g. of *o*-diphenylbenzene, but the greater part of this fraction consisted of an uncrystallizable sirup.

Triphenylene.—The fraction boiling at 225–250° (15 mm.), the bulk of which passed over at about 240°, was recrystallized from a mixture of chloroform and methyl alcohol, which removed some pale yellow, sirupy material. The product, which melted at 110–115° and was evidently a mixture, was twice recrystallized from chloroform, when colorless needles melting at 199° (corr.) were obtained. The melting point was not changed on recrystallization from acetone. The boiling point was found to be 425° (corr.).

Mol. Wt. Ebullioscopic method; solvent, benzene. Solvent, 24.546. Subs., 0.2498, 0.4898, 0.6475, 0.7871; Δt , 0.1169°, 0.2264°, 0.2965°, 0.3691°. Calcd. for $C_{18}H_{12}$: 228. Found: 227, 230, 232, 227.

On mixing a cold saturated solution in acetone with a saturated solution of picric acid in the same solvent, the picrate separated as a yellow crystalline precipitate. On recrystallization from acetone it formed long, yellow needles which melted at 223° (corr.). This picrate was identified with the triphenylene picrate obtained from the residues of biphenyl produced by the action of a red-hot wire on benzene.

***o,o'*-Diphenylbiphenyl.**—The chloroform mother liquor from the triphenylene was evaporated to dryness and the residue recrystallized from acetone. Two types of crystal were obtained, the long, fine needles of triphenylene and some more massive pyramids. After decanting the mother liquor, the mixture was gently stirred for a few seconds with cold acetone; the solubilities of the two compounds appeared to be about the same, but the fine needles dissolved more rapidly. By repeating this procedure three or four times, all the triphenylene was removed and the residual crystals were finally recrystallized from acetone. The product forms large tetragonal or rhombic pyramids which melt at 118° and boil at 420° (corr.). It is readily soluble in acetone and chloroform and almost insoluble in cold methyl alcohol. It appears to form no compound with picric acid.

Anal. Subs., 0.1980, 0.1957: CO_2 , 0.6845, 0.6767; H_2O , 0.1056, 0.1023. Calcd. for $C_{24}H_{18}$: C, 94.12, H, 5.88. Found: C, 94.31, 94.29; H, 5.95, 5.85.

Mol. Wt. Ebullioscopic method; solvent, benzene. Solvent, 23.905. Subs., 0.2047, 0.4396, 0.5900, 0.7895; Δt , 0.0799°, 0.1619°, 0.2180°, 0.3455°. Calcd.: 306. Found: 298, 296, 295, 292.

The mother liquor from the triphenylene and diphenylbiphenyl on concentration yielded a pale yellow sirup, which was freed of solvent by warming under reduced pressure. It was readily soluble in acetone and chloroform, but only slightly in methyl alcohol; it was indistinguishable from the principal constituent of the fraction collected at 220–225° (15 mm.).

Anal. Subs., 0.2224: CO_2 , 0.7635; H_2O , 0.1173. Found: C, 93.70; H, 5.90.

Synthesis of *o,o'*-Diphenylbiphenyl.—An intimate mixture of 4 g. of *o*-iodobiphenyl, prepared from fluorenone by the method of Graebe and Rateanu,²⁰ and 5 g. of copper

²⁰ Graebe and Rateanu, *Ann.*, 279, 257 (1894).

bronze (Naturkupfer C) was heated at 260° for 20 minutes. The product was cooled and extracted with acetone in a Soxhlet apparatus. The extract was boiled with charcoal, filtered and concentrated; large, colorless pyramids separated on cooling. The yield was 1.5 g. (72% of the calculated amount) of a product melting at 115–116°. On recrystallization from a mixture of alcohol and benzene it melted at 116–117°, and a mixture of it with the *o,o'*-diphenylbiphenyl obtained from chlorobenzene showed no change in melting point.

Synthesis of *o*-Diphenylbenzene.—A mixture of 5 g. of *o*-iodobiphenyl, 10 g. of *o*-iodobenzene and 15 g. of copper bronze (Naturkupfer C) was heated in a sealed tube at 240° for three hours. The product solidified on cooling. It was extracted with benzene in a Soxhlet apparatus and the extract boiled with charcoal, filtered and freed from solvent by distillation. The residue was distilled under 2 mm. pressure and the following fractions were collected: 110–130°, 2 g.; 160–170°, 2 g.; above 200°, 1 g. The fraction boiling at 110–130° (2 mm.) was recrystallized from alcohol and found to consist of biphenyl. The fraction boiling at 160–170° was dissolved in warm methyl alcohol; on cooling, large prisms were obtained which melted at 55° and boiled at 320–325° (uncorr.). A mixture of this material with the *o*-diphenylbenzene obtained from chlorobenzene melted at 55–56°; a sample became oily at room temperature on mixing with biphenyl. The fraction boiling above 200° was washed with methyl alcohol, and the undissolved crystals, amounting to 0.5 g., were found to be identical with the *o,o'*-diphenylbiphenyl obtained by heating copper bronze and *o*-iodobiphenyl alone.

Action of Sodium on Chlorobenzene in the Presence of Toluene.—A. To a mixture of 2500 g. (22.2 moles) of chlorobenzene and 4600 g. (50 moles) of toluene was added 460 g. of sodium, exactly as in the previous experiment. The mixture was steam distilled and the distillate separated and fractionated. The resulting benzene was estimated as 603 g. (7.74 moles). The residual tar, on long standing, partially crystallized but it was not further examined.

B. To a suspension of 460 g. (20 g.-atoms) of sodium in 4600 g. (50 moles) of boiling toluene was added, with stirring, 2500 g. (22.2 moles) of chlorobenzene at such a rate that the mixture boiled vigorously but without loss of vapor. This required about five hours. The products were worked up exactly as in the experiment in which chlorobenzene alone was employed. Estimation of the benzene in the steam distillate showed the presence of 725 g. (9.3 moles). Distillation of the high-boiling portions under 20 mm. pressure yielded the following fractions: up to 135°, 14 g. of oil; 135–150°, 120 g. of oil; 150–170°, 19 g. of oil; 170–200°, 7 g. of solid; 200–230°, 84 g. of solid; 230–270°, 82 g. of semi-solid; 270–300°, 53 g. of solid; residue, 122 g.

Oxidation Experiments.—The only fraction which was closely investigated was that boiling at 135–150° (20 mm.) which should correspond to the biphenyl fraction in the first experiment. A 10g. sample of this material was stirred for eight hours with a boiling solution of 18 g. of potassium permanganate in 1500 cc. of water. After decolorizing the unchanged permanganate by the addition of alcohol, the precipitate was filtered off and washed with ether; the filtrate was shaken with ether, separated, concentrated to 100 cc. and acidified with hydrochloric acid. In this way, 2.0 g. of a mixture of acids melting at 115–180° was obtained. This was recrystallized from carbon tetrachloride, when *p*-phenylbenzoic acid (m. p., 223–224°) was obtained. The ethereal solution was evaporated to dryness, and the residue treated with hydroxylamine hydrochloride and alkali, when 2.0 g. of crude benzophenone-oxime (m. p., 138–140°) was obtained. On recrystallization from alcohol this appeared as long needles melting at 141–142°. Steam distillation of the alkaline mother liquor yielded no biphenyl.

In another experiment, 10 g. of the same fraction was oxidized by means of 30 g. of chromic acid in 75 cc. of glacial acetic acid. The reaction mixture was cooled and poured into 2 liters of water. After standing overnight the crystals were separated and extracted

with 15 cc. of warm petroleum ether (35–60°). The extract deposited 2.3 g. of almost pure benzophenone; m. p., 49°.

Migration of Sodium in Sodium *p*-Tolyl

To 7.7 g. of mercury di-*p*-tolyl in 200 cc. of dry benzene was added 10 g. of metallic sodium in clean shavings. After standing for a month, the brown suspension was decanted from the sodium amalgam and unchanged sodium, and a stream of dry carbon dioxide was passed through the mixture. Reaction began immediately with evolution of heat. After an hour the mixture was warmed on a steam-bath and carbon dioxide passed through the gently boiling solution for four hours, when cold water was added and the upper layer shaken with dilute alkali. The combined aqueous solutions were acidified. The resulting precipitate was found to consist almost entirely of *p*-toluic acid. The weight was 1.64 g. On recrystallization from benzene it melted at 176–177°.

The aqueous filtrate was extracted with benzene; on evaporation to dryness a slightly oily solid remained which on recrystallization from water yielded 1.65 g. of benzoic acid. After sublimation and recrystallization from petroleum ether, and finally from water, it melted at 116–118°. This melting point was unchanged on mixing with authentic benzoic acid. A sample also yielded benzanilide possessing the correct melting point which was unchanged on mixing with benzanilide of known purity.

The first mother liquor from the benzoic acid, which possessed a strong odor of phenylacetic acid, was neutralized and concentrated to a small bulk. Addition of hydrochloric acid yielded an oil which solidified on cooling in ice. After repeated crystallization from water, there was obtained 0.20 g. of phenylacetic acid. This was identified by comparison with authentic phenylacetic acid.

Action of Sodium on Chlorobenzene in the Presence of Dimethylaniline

To a suspension of 520 g. (22.6 g.-atoms) of sodium in 4600 g. of hot dimethylaniline was gradually added, with stirring, 2500 g. (22.2 moles) of chlorobenzene at such a rate that the mixture boiled continually. When the addition was complete, the mixture was allowed to cool, and the slight excess of sodium brought into reaction by adding methyl alcohol, after which 3 l. of water was added. The aqueous solution was separated by siphon, and 1.5 liters more water added to the oily portion. This mixture was then distilled through a column until the temperature of the vapor rose to 99°. The distillate was acidified with hydrochloric acid, and the undissolved oil washed with water and finally with 50% sulfuric acid. The benzene so obtained weighed 845 g. (10.8 moles) and distilled entirely at 79–80°. The residue from which the benzene had been distilled was treated with excess of dil. hydrochloric acid and the insoluble portion warmed with a dil. solution of hydrochloric acid in 30% methyl alcohol. The united acid solutions were neutralized with sodium hydroxide and the resulting oil fractionally distilled under reduced pressure with the use of a column, when the bulk of the unchanged dimethylaniline was recovered in pure condition. The residue from this distillation, amounting to about 85 g., was distilled from a small flask, when it gave the following fractions: 235–271°, 5 g.; 271–282°, 9 g.; 282–292°, 7 g.; 292–296°, 7 g.; 296–304°, 7 g.; 304–308°, 11 g.; 308–315°, 10 g.; 160–190° (16 mm.), 15 g.; 190–280° (16 mm.), 5 g.; residue, 5 g. The last two fractions partially crystallized on cooling; the bulk of the crystallizable material appeared to pass over between 185 and 195° under 16 mm. pressure. The fraction boiling at 304–308° was examined independently; it was soluble in fairly strong acids but was partially precipitated on dilution. A solution in dil. sulfuric acid developed an intense fuchsin color on the addition of dichromate solution; the color was destroyed on warming and an odor of benzaldehyde developed. Benzylmethylaniline was found to behave somewhat similarly, although its solution in dil.

sulfuric acid was considerably less hydrolyzed on further dilution, while on the addition of dichromate a yellow-red color was formed; this, when the mixture was warmed, turned green, and an odor of benzaldehyde developed.

The tar which remained after extraction with dil. hydrochloric acid weighed 960 g. and was found to contain 2.54% of nitrogen, corresponding to 1.75 g. equivalents. On steam distillation it yielded a very small quantity of biphenyl. It was found to be soluble in glacial acetic acid; the solution on exposure to air developed a blue color reminiscent of that obtained by the oxidation of certain derivatives of diphenylamine.

Action of Sodium on *n*-Heptyl Bromide

To 1074 g. of *n*-heptyl bromide (6 moles) heated to about 150° was added sodium in small quantities, with vigorous stirring, at such a rate that the mixture boiled briskly but under control. When about 100 g. of sodium had been added, the mixture became too thick to stir satisfactorily; it was allowed to cool, water was added and the oil separated, dried, and again treated with sodium until no further reaction took place. The unreacted sodium was removed by the addition of alcohol, the salts were dissolved with water and the oil distilled through a small bubbler column; the material distilling up to 101° (after which the temperature rose very rapidly) was collected. The distillate was well washed with water to remove methyl alcohol and treated with a solution of bromine in hydrobromic acid until a permanent excess of bromine was present. After it had been washed with sodium sulfite solution, the resulting liquid was distilled, in the presence of water, through a bubbler column and the distillate collected until only a small proportion of oil passed over with the water. The distillate was separated and the oil shaken repeatedly with concd. sulfuric acid and distilled under atmospheric pressure. It boiled entirely at 96–99° and was practically pure heptane; wt., 50 g. The brominated oil, which was only slightly volatile with steam, was distilled under reduced pressure when it passed over entirely at 103–104° (10 mm.); wt. 79 g. Its properties corresponded to those given in the literature for heptylene bromide.

The residue from which the heptane and heptylene had been distilled was fractionated under reduced pressure, when 395 g. of tetradecane boiling at 115–117° (10 mm.) was obtained. This solidified in a freezing mixture and melted at 4–4.5°. The high-boiling residue on further fractionating yielded a main fraction boiling at 185–195° (10 mm.) and a small quantity of a yellowish oil of still higher boiling range. Analysis of the fraction boiling at 185–195° (10 mm.) showed the presence of 84.3–84.4% of carbon and 14.4–14.6% of hydrogen. It was suspected that the deficiency was due to the presence of oxygenated impurities; the fraction was accordingly repeatedly shaken with concd. sulfuric acid until color was no longer imparted to the acid; it then distilled entirely at 340–345° (corr.). The loss on this purification was very slight.

The authors desire to express their gratitude to Professor Gomberg at the University of Michigan for permitting some of the experiments and analyses to be carried out in his Laboratory.

Summary

1. The action of sodium upon boiling chlorobenzene leads to the formation of benzene, biphenyl, *o*-diphenylbenzene, *p*-diphenylbenzene (minute amount), triphenylene, *o,o'*-diphenylbiphenyl, together with unidentified resinous and tarry hydrocarbons.

2. The reaction is conveniently interpreted by assuming the intermediate formation of free phenyl and *o*-phenylene radicals.

3. The action of sodium upon *n*-heptyl bromide leads to the formation of heptane, heptylene, tetradecane, a heneicosane of undetermined structure, and hydrocarbons of higher molecular weight. This type of reaction appears to be general for the bromides of primary alcohols.

4. The action of sodium upon chlorobenzene in the presence of an excess of toluene leads to the formation of nearly 50% of benzene; biphenyl is not produced, diphenylmethane, *p*-methylbiphenyl being formed in its stead. The reaction takes an analogous course in the presence of an excess of dimethylaniline, the condensation products containing nitrogen.

5. The constitution of *o*-diphenylbenzene and *o,o'*-diphenylbiphenyl has been confirmed by synthesis.

SOME CYCLOHEXYL-PHENOLS AND PHENOL ETHERS

BY J. F. BARTLETT¹ WITH C. E. GARLAND

RECEIVED JUNE 4, 1927

PUBLISHED AUGUST 5, 1927

Considering the many recent developments in the preparation of alkyl and aryl phenols² and the studies made of their germicidal properties, it was decided to prepare some of the cyclohexyl derivatives in order that they might be compared with those already known.

Previous to this time, cyclohexyl-phenol³ is the only derivative of this particular type recorded in the literature. Wuyts prepared this compound

¹ This communication is an abstract of a thesis submitted by J. F. Bartlett, in partial fulfillment of the requirements for the degree of Master of Arts in Chemistry, at West Virginia University.

² The chief contributions have been made by the following investigators. (a) Johnson and Hodge, *THIS JOURNAL*, **35**, 1014 (1913). (b) Johnson and Lane, *ibid.*, **43**, 348 (1921). Leonard, *J. ³ Wuyts, *Bull. soc. chim. Belg.*, **26**, 304 (1912).

by condensing cyclohexanol with a large excess of phenol in the presence of toluene-4-sulfonic acid. The melting point recorded is 128°.

Applying the method Klarmann^{2d} used in similar reactions, cyclohexyl chloride was condensed with resorcinol, anisole and phenetole in the presence of anhydrous aluminum chloride. For the preparation of cyclohexyl-phenol, Klarmann's modification of the method employed by Liebmann⁴ was used. Cyclohexyl chloride was condensed with phenol in the presence of anhydrous aluminum chloride. It was also prepared from cyclohexyl-anisole by hydrolysis with constant-boiling hydrobromic acid. In each case the compound was the same as that prepared by Wuyts, as indicated by the melting point.

The phenol coefficients⁵ of cyclohexyl-resorcinol and cyclohexyl-phenol were determined. The solubility of cyclohexyl-resorcinol in distilled water is 51 mg. per 100 cc. at 25°. Using this solution, a phenol coefficient of 23-27 was found. Apparently the cyclic structure of the side chain reduces the phenol coefficient, as compared with that of *n*-hexyl-resorcinol (46-56), to near that of the *isohexyl*-resorcinol recorded by Dohme, Cox and Miller, which is given as 27. The solubility of cyclohexyl-phenol in distilled water is 6 mg. per 100 cc. at 25°. At this concentration no germicidal properties were indicated.

Work in the field of cyclohexyl-phenols and derivatives is being continued.

Experimental Part

Cyclohexyl-resorcinol. $C_6H_5(C_6H_{11})(OH)_2(1,2,4)$.—Cyclohexyl chloride was prepared by treating cyclohexanol with concd. hydrochloric acid, and refluxing slowly while dry hydrogen chloride was passed through the mixture, in order to increase the yield. This was continued for a period of about three hours. The upper layer of cyclohexyl chloride was separated, washed first with dil. sodium carbonate solution and then with water. After drying with calcium chloride it was subjected to fractional distillation and a yield of 65% was obtained; b. p., 141-143° at atmospheric pressure.

For the condensation of cyclohexyl chloride with resorcinol a two-liter flask was fitted with a reflux condenser, dropping funnel and a mercury-seal stirrer. Ninety g. of resorcinol dissolved in 450 cc. of freshly distilled nitrobenzene, together with 18 g. of aluminum chloride (anhydrous) was placed in the flask. Seventy-seven g. of cyclohexyl chloride was slowly added while the reaction mixture was rapidly stirred and slowly heated to 70° on the water-bath. After about four hours, when the hydrogen chloride was practically all liberated, the contents of the flask were poured onto ice and allowed to cool. A quantity of ether equal in volume to the dark oily liquid was added and this solution extracted with 10% sodium hydroxide until it produced no further coloration. The alkaline solution was made acid with hydrochloric acid and steam distilled to remove traces of nitrobenzene. On cooling, white, crystalline plates of cyclohexyl-resorcinol separated, together with a quantity of tarry material which settled to the bottom of the flask. On standing for several days, the dried crystals turned slightly

⁴ Liebmann, *Ber.*, 14, 1842 (1881).

⁵ Phenol coefficients were determined according to the method of the Hygienic Laboratory, by Dr. R. S. Spray of the West Virginia University School of Medicine. For his cooperation the thanks of the authors are due.

brown and a solution of the substance in water, on long standing, developed a fluorescence. In alcohol and ether the substance is readily soluble, and the sodium salt is soluble in water; m. p., 124–125°; yield, about 5%.

Anal. Calcd. for $C_{13}H_{16}O_2$: C, 74.95; H, 8.39. Found: C, 74.75, 74.43; H, 8.28, 8.87.

Cyclohexyl-anisole. $C_6H_4(C_6H_{11}).OCH_3(1,4)$.—Forty-two g. of anisole was condensed with 30 g. of cyclohexyl chloride in the presence of 6 g. of anhydrous aluminum chloride. The procedure was the same as with cyclohexyl-resorcinol except that an additional solvent was not used. The oily liquid from the reaction was dried and subjected to distillation at 16 mm. pressure. The distillation commenced at 134° and continued to 200°. The distillate was then subjected to fractional distillation at 16 mm. and analyzed. This, together with the conversion to the free phenol, indicated that the larger fraction which came over between 146 and 148° was the cyclohexyl-anisole. This material solidified when placed in an ice-bath but remained liquid at room temperature. A very small amount of higher-boiling fraction was obtained which has not yet been identified; yield of 146–148° fraction, 15–20%; d_4^{20} , 1.0209; d_4^{25} , 1.0004; n_D^{25} , 1.5305; molecular refraction: calcd. 58.07, found: 58.71. The molecular weight was determined by the cryoscopic method, using benzene as a solvent.

Anal. Calcd. for $C_{13}H_{18}O$: C, 82.05; H, 9.54. Found: C, 82.33, 82.22; H, 9.70, 9.55.

Mol. wt. Calcd. for $C_{13}H_{18}O$: 190.14. Found: 184.8.

Cyclohexyl-phenetole. $C_6H_4(C_6H_{11}).OC_2H_5(1,4)$.—Thirty-four g. of phenetole was condensed with 30 g. of cyclohexyl chloride in the presence of 6 g. of anhydrous aluminum chloride, the general procedure in this case being the same as that described above. The condensation product on distillation gave one principal fraction 155–157° (16 mm.). After standing for several days it mostly solidified to very small prismatic needles; yield, 12%; n_D^{25} , 1.5262.

Anal. Calcd. for $C_{14}H_{20}O$: C, 82.30; H, 9.86. Found: C, 82.41, 82.17; H, 10.10, 9.80.

Cyclohexyl-phenol. $C_6H_4(C_6H_{11}).OH(1,4)$.—*Method I.* This phenol was obtained from cyclohexyl-anisole by hydrolysis with constant-boiling hydrobromic acid mixed with glacial acetic acid. It was purified by recrystallization of the sodium salt from water solution. The sodium salt on decomposition with acid gave a white, crystalline solid; m. p., 128°; yield, 14%.

Method 2. Cyclohexyl-phenol was also prepared by condensing cyclohexyl chloride with phenol in the presence of fused zinc chloride. Ninety g. of phenol was condensed with 118 g. of cyclohexyl chloride in the presence of 118 g. of fused zinc chloride. The reaction mixture was heated in a water-bath until the evolution of hydrogen chloride could no longer be observed. It was then poured onto ice and from the oily liquid the sodium salt of the phenol was obtained by alkaline extraction. The phenol was further purified as under the first method; yield, 20%; m. p., 128°.

Anal. Calcd. for $C_{13}H_{18}O$: C, 81.79; H, 9.16. Found: C, 81.67; H, 9.11.

The benzoyl ester of the cyclohexyl-phenol was prepared by the Schotten-Baumann reaction. Recrystallization from alcohol gave a white, crystalline solid; m. p., 114–114.5°.

Anal. Calcd. for $C_{19}H_{26}O_2$: C, 81.38; H, 7.19. Found: C, 81.04, 80.96; H, 7.20, 7.21.

Summary

1. Four new compounds have been prepared; cyclohexyl-resorcinol, cyclohexyl-anisole, cyclohexyl-phenetole and the benzoyl ester of cyclo-

hexyl-phenol. The properties of these compounds have been determined. Cyclohexyl-phenol, which has been prepared previously, was obtained by two new methods.

2. Cyclohexyl-phenol was not found to have any germicidal properties in water solution because of its limited solubility. Cyclohexyl-resorcinol gave a phenol coefficient of 24-27.

SELECTIVE REDUCTION OF FURFURACROLEIN BY MEANS OF PLATINUM-OXIDE PLATINUM BLACK AND HYDROGEN. XVI¹

BY R. H. BRAY² WITH ROGER ADAMS

RECEIVED JUNE 6, 1927

PUBLISHED AUGUST 5, 1927

In a previous paper it was shown that aldehydes³ could not be reduced to alcohols with hydrogen and platinum-oxide platinum black unless some promoter such as a ferrous salt was present. As these promoters for the reduction of aldehydes are poisons toward the reduction of olefins, the study of the reduction of α,β unsaturated aldehydes,⁴ in particular cinnamic aldehyde and citral, resulted in the discovery that by using a ferrous salt, together with a small amount of zinc salt, it was possible to reduce quantitatively the aldehyde group to a primary alcohol without affecting the olefin linkages. Cinnamyl alcohol and geraniol, respectively, were produced.

Furfural⁵ was like other aldehydes and the catalytic reduction with platinum-oxide platinum black and hydrogen would not take place unless ferrous salt or some such promoter was present. The primary product was furyl carbinol formed upon the absorption of one molecular equivalent of hydrogen. If the reduction was allowed to go until no more absorption of hydrogen took place, ordinarily slightly over four molecular equivalents of hydrogen were absorbed, and there resulted a mixture of tetrahydro-furyl carbinol, pentane-diol-1,2, pentane-diol-1,5, and a small amount of *n*-amyl alcohol, the latter three substances being produced by scission of the ring.

In the present investigation the work on selective reduction has been

⁵ Kaufman and Adams, *THIS JOURNAL*, **45**, 3029 (1923).

extended to furfuracrolein (I) which combines certain conditions present in furfural and in α,β unsaturated aldehydes. This compound, as might be expected, could not be reduced unless a promoter was present. The presence of ferrous sulfate caused the absorption of hydrogen to take place although, as in the case of the cinnamic aldehyde, the reaction did not stop after one molecular equivalent had reacted, but more hydrogen was absorbed to a maximum of 4.3–4.4 molecular equivalents. If the reaction mixture was distilled after one molecular equivalent of hydrogen was absorbed no pure product was obtained. When a small amount of zinc acetate, in addition to the ferrous salt was present, however, the absorption of hydrogen stopped completely after one molecular equivalent reacted and a single product resulted—furyllallyl alcohol (II).

An attempt was made to isolate pure products after two molecular equivalents of hydrogen had been absorbed, using merely the ferrous salt to promote the reaction, but the results were unsuccessful. After the absorption of three molecular equivalents of hydrogen, two pure products could be separated from the reaction mixture by distillation, furylpropyl alcohol (III) and tetrahydrofuryllallyl alcohol (IV), the former in the larger quantities. Finally, after all of the hydrogen was absorbed which would react, a good yield of tetrahydrofurylpropyl alcohol (V) resulted, with small amounts of a heptane-diol (VI), which was probably the 1,4-isomer.

Obviously the mechanism consists first in the absorption of hydrogen to reduce the aldehyde group. This is followed by the reduction either of the olefin groups in the furane nucleus or of the olefin linkage in the side chain. Since the yield of tetrahydrofuryllallyl alcohol was much smaller than that of the furylpropyl alcohol, the tendency for the aliphatic olefin linkage to reduce is greater than of the ring olefin linkages. The furylpropyl alcohol is then reduced for the most part to the tetrahydro derivatives, but a little of it, as with furylcarbinol, is reduced with splitting of the oxygen ring and formation of a diol.

It was assumed that tetrahydrofurylallyl alcohol is actually the substance which was obtained and not one of the possible isomers. Although there are five isomeric compounds which agree with the analyses, the *cis* or *trans* form of the tetrahydrofurylallyl alcohol and three isomeric dihydrofuryl propyl alcohols (VII, VIII, IX), the extreme difficulty in isolation of a dihydrofuryl derivative by any method of reduction of a furane derivative renders the latter compounds very unlikely products.

Whether the compound in hand is the *cis* or *trans* modification of tetrahydrofurylallyl alcohol has not been determined.

The heptane diol isolated is probably the 1,4-isomer, as can be seen by comparing its constants and those of its derivatives with the 1,7-isomer prepared by another method.⁶

TABLE I
PHYSICAL CONSTANTS OF GLYCOLS

	Heptane-diol 1,4	Heptane diol 1,7
Glycol	B p , 126 5-128 5° (4 mm) , 240-245° (750 mm) , n_D^{25} , 1 4510, d_{20}^{20} 0 9559	B p , 262° (atm)
Diacetate	B p , 113-113 5° (1 mm) , 249-252° (748 mm) , n_D^{25} , 1 4268, d_{20}^{20} 0 9934, d_0^0 , 1 0135	B p , 274° (atm) , d_0^0 , 1 0219
Phenylurethan	Oil	M p , 134°
α -Naphthylurethan	M p , 81-82°	

The lower boiling point would indicate the 1,4-isomer, since in isomeric straight-chained glycols the one with the hydroxyl groups closer together invariably boils lower. Moreover, the indices of refraction of glycols increase as the hydroxyl groups are situated further apart. The values are of the same order for 1,2-glycols, for 1,5-glycols, etc., regardless of the number of carbon atoms in the molecule. From the data given below, therefore, the indications are for the 1,4-isomer.

Acetates and α -naphthylurethan derivatives of the various compounds isolated were prepared and identified.

Experimental

Materials.—The platinum oxide was prepared according to the method of Adams and Shriner⁷ from C. P. chloroplatinic acid.

The furfuracrolein was prepared by the method of Konig and Hey⁸ by condensation of furfural with acetaldehyde. In order to purify the product, fractional distillation under diminished pressure was found much more satisfactory than steam distillation followed by crystallization. It was absolutely necessary that the material be freshly distilled before the reduction was started or else the reaction took place only very slowly or not at all.

Reduction of Furfuracrolein (I).—In a typical run 0.2 g. of platinum oxide, 0.00002 mole of ferrous sulfate, 100 cc. of alcohol and 24.4 g. of furfuracrolein were used. The platinum oxide was reduced to platinum black in half of the alcohol, then the ferrous sulfate, the furfuracrolein and the rest of the alcohol were added. The reduction was carried out under 2.5–3 atmospheres' pressure with hourly reactivations with air or oxygen for the first seven hours and then occasional reactivations thereafter. The time for the complete reduction, during which 4.2–4.4 molecular equivalents of hydrogen were absorbed, was approximately 24 hours.

In the preparation of furylallyl alcohol, 0.00003 mole of zinc acetate and 0.0002 mole of ferrous sulfate were used in place of the amount of ferrous sulfate in the typical run just described. The reduction was thus slowed down and it practically stopped after one molecular equivalent of hydrogen had been absorbed. The time for this reduction was about 9.5 hours as compared with 4.5 hours for the absorption of one molecular equivalent when no zinc salt was added.

The products were isolated by means of fractional distillation under diminished pressure. The alcohols with unsaturated side chains always yield a certain amount of red, resinous residue when distilled, indicating partial decomposition or polymerization.

Furylallyl Alcohol (II).—Upon the reduction of 24.4 g. of furfuracrolein in presence of iron and zinc salts as described above until one molecular equivalent of hydrogen was absorbed, 19 g. of pure product was isolated. The furylallyl alcohol boils at 108–110° at 4 mm.; n_D^{27} , 1.5520; d_{20}^{20} , 1.1439. Upon distillation it decomposes somewhat and always leaves a high-boiling residue. On standing it turns yellow, then red and finally thickens. By the action of acetic anhydride no ester was obtained, as decomposition apparently took place.

Anal. Subs., 0.1480: CO₂, 0.3668; H₂O, 0.0890. Calcd. for C₇H₈O₂: C, 67.72; H, 6.50. Found: 67.61; 6.73.

α -Naphthyl Urethan of Furylallyl Alcohol.—The α -naphthyl urethan derivative was prepared according to the directions of Bickel and French⁹ from the alcohol and α -naphthyl isocyanate. The product crystallizes from ligroin in white rosetts. When pure it melts at 93–93.5°.

Anal. Subs., 0.1000: 4.60 cc. of 0.0714 N NaOH. Calcd. for C₁₈H₁₈O₂N: N, 4.78. Found: 4.60.

Furylpropyl Alcohol (III).—From a reduction of furfuracrolein using ferrous sulfate and stopping the reaction after approximately 3 molecular equivalents of hydrogen were absorbed, there was obtained by fractionation two products. One, the lower-distilling,

⁸ Konig and Hey, *Frdl.*, **13**, 110 (1923).

⁹ Bickel and French, *THIS JOURNAL*, **48**, 747 (1926).

which proved to be furylpropyl alcohol, boils at 90–91° at 4 mm.; 201–208° at 747 mm.; n_D^{25} , 1.4760; d_4^{20} 1.0613. The yield was approximately 50 per cent. of the calculated amount. The product gradually turns yellow on standing.

Anal. Subs., 0.1584: CO₂, 0.3859; H₂O, 0.1158. Calcd. for C₇H₁₀O₂: C, 66.63, H, 7.99. Found: 66.46, 8.18.

α -Naphthyl Urethan of Furylpropyl Alcohol.—It forms white crystals from ligroin, m. p., 49°.

Anal. Subs., 0.1500: 7.06 cc. of 0.0714 N NaOH. Calcd. for C₁₈H₁₉O₂N: N, 4.71. Found: 4.71.

Furylpropyl Acetate.—A mixture of 10 cc. of alcohol and an excess of acetic anhydride was refluxed for 3.5 hours. The pure ester boils at 92° at 2 mm.; 217–218° at 747 mm.; n_D^{25} , 1.4553; d_4^{20} 1.0601. It turns yellow on standing.

Anal. Subs., 0.1410: CO₂, 0.3299; H₂O, 0.0927. Calcd. for C₉H₁₂O₂: C, 64.26; H, 7.19. Found: 63.83, 7.36.

Tetrahydrofurylallyl Alcohol (IV).—The higher-boiling material obtained after separating the furylpropyl alcohol proved to be tetrahydrofurylallyl alcohol. It boils at 100–101° at 4 mm.; n_D^{25} , 1.4675; d_4^{20} , 1.0317. The yield of pure product was approximately 10 per cent. It turns red on standing. It was impossible to obtain solid derivatives with α -naphthyl isocyanate, phenyl isocyanate, or 3,5-dinitrobenzoyl chloride.

Anal. Subs., 0.1613: CO₂, 0.3853; H₂O, 0.1360. Calcd. for C₇H₁₀O₂: C, 65.59; H, 9.44. Found: 65.17, 9.43.

Tetrahydrofurylallyl Acetate.—The acetate boils at 90–91° at 2 mm.; n_D^{25} , 1.4468; d_4^{20} , 1.0374. It turns yellow-orange on standing.

Anal. Subs., 0.1168: CO₂, 0.2710; H₂O, 0.0845. Calcd. for C₉H₁₄O₂: C, 63.50; H, 8.29. Found: 63.30, 8.10.

Tetrahydrofurylpropyl Alcohol (V).—When the reductions in the presence of a little ferrous sulfate were run to completion with the absorption of 4.2–4.4 molecular equivalents of hydrogen, the chief product of reaction was tetrahydrofurylpropyl alcohol in yields of about 60 per cent. It boils at 106–107° at 2 mm.; 221° at 747 mm.; n_D^{25} , 1.4540; d_4^{20} , 1.0032. The higher-boiling fraction was a heptane-diol described below.

Anal. Subs., 0.1158: CO₂, 0.2732; H₂O, 0.1126. Calcd. for C₇H₁₄O₂: C, 64.57; H, 10.84. Found: 64.36, 10.88.

3,5-Dinitrobenzoate of Tetrahydrofurylpropyl Alcohol.—By warming molecular equivalents of the alcohol and 3,5-dinitrobenzoyl chloride on a water-bath, then adding water, the ester was obtained which, on purification from dil. alcohol, melts at 65.5–66°.

Anal. Subs., 0.2000: 17.2 cc. of 0.0714 N NaOH. Calcd. for C₁₄H₁₆O₇N₂: N, 8.64. Found: 8.60.

Tetrahydrofurylpropyl Acetate.—This product boils at 99° at 2 mm.; 228.5–229° at 750 mm.; n_D^{25} , 1.4380; d_4^{20} , 1.0207.

Anal. Subs., 0.1983: CO₂, 0.4546; H₂O, 0.1673. Calcd. for C₉H₁₆O₂: C, 62.75; H, 9.37. Found: 62.54, 9.44.

Heptane-diol 1,4 (VI).—The high-boiling fraction from the complete reduction of furfuracrolein proved to be a heptane-diol and was obtained in about 10 per cent. yields. It boils at 126.5–128.5° at 4 mm.; 240–245° at 750 mm.; n_D^{25} , 1.4510; d_4^{20} , 0.9559. It is completely miscible in water.

Anal. Subs., 0.1894: CO₂, 0.4423; H₂O, 0.2039. Calcd. for C₇H₁₆O₂: C, 63.58; H, 12.20. Found: 63.71, 12.05.

α -Naphthyl Urethan of Heptane-diol.—This product on crystallization from ligroin melts at 81–82°.

Anal. Subs., 0.1000: 5.60 cc. of 0.0714 *N* NaOH. Calcd. for $C_{21}H_{26}O_4N_2$: N, 5.95. Found: 5.60.

Heptane-diol Diacetate.—The substance boils at 113–113.5° at 1 mm.; 249–252° at 748 mm.; n_D^{25} , 1.4268; d_{20}^{20} , 0.9934; d_4^{20} 1.0135.

Anal. Subs., 0.1019: CO_2 , 0.2280; H_2O , 0.0876. Calcd. for $C_{11}H_{20}O_4$: C, 61.08; H, 9.28. Found: 61.05, 9.62.

Summary

1. The reduction of furfuracrolein in alcohol solution was carried out using platinum-oxide platinum black as a catalyst and a little ferrous sulfate as a promoter. After the absorption of 3 molecular equivalents of hydrogen, there was isolated furylpropyl alcohol and tetrahydrofurylallyl alcohol. After absorption of 4.2–4.4 molecular equivalents of hydrogen, the maximum amount taken up, there was obtained tetrahydrofurylpropyl alcohol and a heptane-diol.

2. An attempt to isolate products after the absorption of one molecular equivalent or two molecular equivalents of hydrogen was unsuccessful. If the reduction was carried out in the presence of ferrous sulfate and zinc acetate, however, the reduction stopped automatically after one molecular equivalent of hydrogen had been absorbed and pure furylallyl alcohol was readily obtained.

3. The acetates of many of the alcohols were prepared and the α -naphthyl urethans of some of them.

ULTRAVIOLET ABSORPTION SPECTRA OF CYCLOHEXENE, ETHYL ETHER, METHYL-NORMAL-AMYL ETHER AND ETHYLENE CHLOROHYDRIN. A CORRECTION TO THE ARTICLE OF THIS TITLE BY SMITH, BOORD, ADAMS AND PEASE

BY HENRY DE LASZLO¹

RECEIVED JUNE 8, 1927

PUBLISHED AUGUST 5, 1927

The ultraviolet absorption spectra of a large number of colorless aliphatic and aromatic compounds have been studied by Henri and his co-workers. One of the main results of this very careful examination was that while benzene possesses some very well marked bands in the region $\lambda 2600 \text{ \AA.} - \lambda 2400 \text{ \AA.}$, the saturated cyclic and open-chain aliphatic hydrocarbons are transparent in this portion of the spectrum. Even decahydronaphthalene² absorbs only from 2300 \AA. downwards. The intro-

² De Laszlo, *Proc. Roy. Soc. (London)*, 111A, 376 (1926).

duction of one double bond in an otherwise saturated molecule gives rise to only broad absorption bands both in vapor and in solution.

All saturated aliphatic alcohols so far examined show no absorption above $\lambda 2400 \text{ \AA.}$; below this they all have a very broad absorption band, the position of whose maximum varies from $\lambda 2200 \text{ \AA.}$ to $\lambda 2350 \text{ \AA.}$, passing from methyl to butyl alcohol. The introduction of a halogen does not, as a rule, alter the general appearance of the spectrum, but if any bands were present in the original substance, these will be displaced toward the visible³ by an amount depending on the size of the molecule. Pure ethyl ether shows no absorption above 2100 \AA. , even the liquid being perfectly transparent in a thickness of 40 mm. In fact, ethyl ether and hexane have been used as solvents for the past years in the measurement of ultraviolet absorption spectra.⁴ The higher aliphatic ethers will show a slight shift toward the red, the absorption limit depending on the number of CH_2 groups in the molecule.

Benzene vapor possesses a very characteristic absorption spectrum consisting of more than 400 lines and band-heads. Of the 200 substances possessing a measurable absorption that have been examined by Henri and his pupils, no two were found to have identical spectra. Nor is this in any degree probable when one considers the very complicated mechanism that gives rise to these spectra.

If, therefore, the work of Smith, Boord, Adams and Pease, published in *THIS JOURNAL*, 1927, page 1335, were correct, then all previous experimental data would be false, which is hardly possible. These four authors find absorption spectra identical to that of benzene for the following substances: cyclohexene, ethyl ether, ethylene chlorohydrin and methyl-*n*-amyl ether. These, however, all fall into the categories mentioned above and will, therefore, show no absorption between $\lambda 2600 \text{ \AA.}$ and $\lambda 2400 \text{ \AA.}$

In order to confirm this, we have examined ethylene chlorohydrin in vapor and in liquid phase.

Experimental Work

One hundred grams of Eastman Kodak Company ethylene chlorohydrin was rapidly distilled in an all-glass Witmer fractionating apparatus. The portion boiling from 128.7 to 128.8° at 764 mm. was collected. This fraction was colorless and possessed only a very faint alcoholic odor. The absorption spectrum of the vapor was then photographed in a layer 15 cm. thick at temperatures varying from 50 to 110° by steps of 10° . No appreciable absorption above 2250 \AA. was to be seen.

The pure liquid was examined in thicknesses of $\frac{1}{10}$ to 5 mm. Con-

³ De Laszlo, *Proc. Roy. Soc.*, (London), 111A, 359 (1926).

⁴ Castille and Henri, *Bull. soc. chim. biol.*, 6, 299-304 (1924).

tinuous absorption below 2300 Å. was observed for a layer 4 mm. thick. A detailed description of the technique will be given in a later article. Hence, it is clear that pure ethylene chlorohydrin does not absorb appreciably above 2300 Å., and then only in a perfectly continuous manner.

Results

It is obvious, therefore, that in every case mentioned by these authors benzene vapor was present. To show how strong the bands of benzene are, we may state that at a pressure of 0.01 mm. the following five band-heads are still visible as five lines: $\lambda 2589.03$ Å., $\lambda 2528.57$ Å., $\lambda 2471.03$ Å., $\lambda 2415.91$ Å., $\lambda 2363.55$ Å. In other words, it has been found that a mass of benzene as small as $1/10,000$ mg. will still give rise to its characteristic band-heads.

All this goes to show how rigorous must be the purification of those compounds whose absorption spectra are to be determined. Thus, in the case of the substances in question, the distillation should be conducted in an all-glass apparatus with an efficient distilling column of the type developed by Witmer.⁵ The boiling-point range should be $\pm 1/10^\circ$ and this fraction should consist of a major portion of the sample. Wherever possible it has been found best to follow this with three or four crystallizations out of optically pure hexane⁴ at about -100° . Chemical purification is also advantageous when possible, as shown in the case of cyclohexane where the benzene present was removed by washing with sulfuric acid. The apparatus for vaporizing and photographing the substance must, of course, be scrupulously clean and is best made entirely of fused quartz so that drastic cleansing with sulfuric and chromic acids may be resorted to.

Aside from the fact that these authors erroneously ascribe the ultra-violet benzene bands to other compounds than benzene, their attempted correlation of the vibrational constants with those of the infra-red bands observed by Ellis⁶ seems open to serious objections; for although the theory of polyatomic band spectra is not yet sufficiently developed to account for the empirical form of Henri's equation for band-heads, involving two sets of integral "quantum numbers," it is probable that the observed vibrational constants are characteristic of the *excited* electronic state. At room temperature we should expect only transitions from the zero vibrational level of the initial (normal) state to be of appreciable intensity in absorption. On the other hand, the infra-red vibration-rotation bands involve only the vibrational terms of the *normal* state, and thus should not in general give constants related to those of the ultra-violet absorption bands. The only satisfactory correlation of electronic

⁵ Dis Zürich Eidg. Tech Hochschule, 1924.

⁶ Ellis, *Phys. Rev*, 27, 298 (1926).

bands with those of the infra-red seems at present to be that given by Birge,⁷ in which the constants of the normal state of carbon monoxide, determined from the emission spectrum, are successfully used to compute the positions of the three strongest vibration-rotation bands.

The agreements which are shown in Table II, p. 1344, of the article under discussion are certainly not convincing. The band of longest wave length in the series found by Ellis is that at 6.7μ , which he interprets as the "fundamental" ($0 \rightarrow 1$) band. The remaining "observed values" in the table should not exist on this interpretation (unless they are combination bands) and, since they are not included by Ellis, must be of small intensity. However, it is precisely the bands of shorter wave length than 6.7μ which require unreasonably large values of n_1 and n_2 for representation by Henri's formula. In fact, with an equation of two independent variables, any other values for the coefficients may be used and still, with suitable assignments of n_1 and n_2 , be made to yield wave lengths which agree as well as those shown. As an illustration we may assume the relation $\nu n = 1000n_1 + 100n_2$ and find the following agreements.

We do not agree, therefore, that the authors have "thus disposed of the physical significance of the ultraviolet absorption of these compounds." There can be no doubt, however, that the use of two sets of integers covering a limited range of small values is significant as permitting a satisfactory representation of a large number of the ultraviolet benzene bands, and also that the single parabolic series of infra-red bands bears a striking resemblance to the analogous bands of diatomic molecules.

Again, if the experimental data and theoretical conclusions given by these authors are correct, namely, that the C-H linkage gives rise to this identical band structure in four different cases, why then are they not obtained for cyclohexane which contains plenty of these linkages?

⁷ Birge, *Phys. Rev.* **28**, 1157 (1926).

Summary

1. It has been proved that the experimental results of Smith, Boord, Adams and Pease are erroneous on the following grounds.

(a) Past experience has shown that bodies of the type examined show only continuous absorption from 2350 Å. to 2000 Å.

(b) The absorption of two out of the four substances concerned has been measured and no evidence of a benzene-like structure such as is claimed has been found.

(c) It has been pointed out that benzene may have been present as an impurity either in the material or apparatus in amounts sufficient to explain the results reported by these authors.

2. Their theoretical deductions have also been shown to be unconvincing.

3. It has been pointed out that in this type of work absolute purity of the compounds examined and cleanliness of the apparatus used are essential.

THE SYNTHESIS OF ALPHA,BETA-DIACYLSTYRENES AND THEIR REACTION WITH HYDROGEN BROMIDE

BY CHARLES F. H. ALLEN AND HARRY B. ROSENER

RECEIVED JUNE 13, 1927

PUBLISHED AUGUST 5, 1927

Japp and his co-workers¹ found that in the presence of alcoholic potassium hydroxide, benzil reacts with acetophenone and forms first an addition product (I), and finally an unsaturated diketone (II), which they called anhydracetophenone benzil or α,β -dibenzoylstyrene.²

We have found that many other dibenzoylstyrenes can be made in this manner, but that the reaction is not general. It was possible to substitute for the acetophenone used by Japp a number of other methyl ketones which had alkyl groups or chlorine atoms in the nucleus, while with other closely related methyl ketones the reaction failed. Thus, di-

¹ Japp and co-workers, *J. Chem. Soc.*, (a) 47, 35 (1885); (b) 51, 430 (1887); (c) 53, 184 (1888); (d) 57, 662 (1890); (e) 71, 1138 (1897); *Ber.*, (f) 18, 187 (1885); (g) 21, 2933 (1888).

² It might better be called phenyldibenzoylethylene, but the naming of compounds substituted in one benzoyl group seems clearer if they are considered as derivatives of styrene.

acylstyrenes were made successfully by condensing benzil with $\text{CH}_3\text{CO}\cdot\text{C}_6\text{H}_5$, $\text{CH}_3\text{COC}_6\text{H}_4\text{CH}_3$ (4), $\text{CH}_3\text{COC}_6\text{H}_3(\text{CH}_3)_2$ (3,4), $\text{CH}_3\text{COC}_6\text{H}_4\text{OCH}_3$ (4), $\text{CH}_3\text{COC}_6\text{H}_3(\text{OCH}_3)_2$ (3,4), $\text{CH}_3\text{COC}_6\text{H}_4\text{Cl}$ (4), $\text{CH}_3\text{COC}_6\text{H}_4\text{Br}$ (4) and $\text{CH}_3\text{COC}_6\text{H}_3(\text{CH}_3)(3)\text{Cl}$ (4). The reaction was tried unsuccessfully with $\text{CH}_3\text{COC}_6\text{H}_3(\text{CH}_3)_2$ (2,4), $\text{CH}_3\text{COC}_6\text{H}_3(\text{CH}_3)_2$ (2,5), $\text{CH}_3\text{COC}_6\text{H}_3(\text{CH}_3)(2)\text{-(i-C}_4\text{H}_7)$ (5), $\text{CH}_3\text{COC}_6\text{H}_3\text{Cl}(2)(\text{CH}_3)$ (5) and $\text{CH}_3\text{COC}_6\text{H}_2(\text{CH}_3)_3$ (2,4,5), the benzil being recovered unchanged. A comparison of the results shows that the reaction fails whenever there is a substituent in the *ortho* position of the acetophenone. This is a peculiar effect of hindrance for which at present there appears to be no adequate explanation. It seems to imply that some kind of addition reaction or complex formation involving the carbonyl group of the methyl ketone must precede condensation.

The styrene derivatives which are obtained in this manner have an ethylenic linkage that is conjugated with two carbonyl groups. They could therefore add substances of the type HX in two ways. Thus, hydrogen bromide could combine with dibenzoylstyrene to form either A or B.

In a series of papers dealing with addition reactions of α,β unsaturated ketones, Kohler³ has shown that while 1:4 addition is prevented if there are two substituent groups in the beta position to the carbonyl group, it takes place readily with compounds having alpha substituents, but at a slower rate than when both positions are unsubstituted. If this relation holds for substances containing conjugated systems of the type in the dibenzoylstyrenes, then the addition product with hydrogen bromide should be A. This is a 1:4 diketone with hydrogen atoms alpha to each carbonyl group; it would, therefore, be expected to lose water easily and form a bromofurane.

We have found that when α,β -dibenzoylstyrene in chloroform or acetic acid solution is treated with hydrogen bromide, the bromofurane (III) separates in nearly the calculated yield. The presence of the third phenyl group appears to favor ring closure because both the saturated bromoketone and the bromofurane can be isolated when hydrogen bromide is added to a chloroform solution of dibenzoylethylene, the corresponding unsubstituted diketone.⁴ We have also found that this transformation

³ Kohler, *Am. Chem. J.*, 1905-1911.

⁴ Paal and Schulze, *Ber.*, 35, 172 (1902). Pratt, *Dissertation*, Harvard University, 1927.

of an unsaturated diketone into a bromofurane is quite general, as it took place with all but one of the diacystyrene derivatives.

Experimental Part

A. Condensation of Benzil and Substituted Acetophenones.—The general directions are as follows. One-twentieth mole of benzil and one-twentieth mole of the ketone are warmed with 5 cc. of methyl alcohol until dissolved. A solution of 0.2 g. of sodium in 25 cc. of methyl alcohol is added, the mixture kept near the boiling point for a few minutes and then allowed to stand overnight. The product is filtered off, washed with dil. alcohol until free from alkali, and recrystallized by dissolving in the smallest possible amount of boiling chloroform and adding an equal volume of methyl alcohol. Glacial acetic acid may also be used for recrystallization. The diketones form small, light yellow prisms almost insoluble in the alcohols and ether, sparingly soluble in acetone, but easily soluble in hot chloroform, acetic anhydride, and acetic acid. Yields, 80–85%.

TABLE I
DERIVATIVES OF α,β -DIBENZOYLSTYRENE

No.	Ketone used ^a (acetophenone derivation)	M. p., °C.	Formula	Analyses			
				Calcd., C	% H	Found, C	% H
II	Acetophenone	129					
IV	4-Methyl-	158	$C_{23}H_{18}O_2$	84.7	5.5	84.3	5.6
V	3,4-Dimethyl- ^b	190	$C_{24}H_{20}O_2$	84.7	5.9	84.5	5.8
VI	4-Methoxy- ^c	177 ^d	$C_{23}H_{18}O_3$	80.7	5.3	80.9	5.2
VII	3,4-Dimethoxy- ^c	177 ^d	$C_{24}H_{20}O_4$	77.4	5.4	77.1	5.2
VIII	4-Chloro-	183	$C_{23}H_{16}O_2Cl$	76.1	4.3	76.2	4.4
IX	4-Chloro-3-methyl- ^c	189	$C_{24}H_{17}O_2Cl$	76.3	4.7	76.3	4.6
X	4-Bromo-	208	$C_{23}H_{17}O_2Br$	64.5	4.1	64.6	4.5

^a Prepared by the method of Adams and Noller, *THIS JOURNAL*, **46**, 1889 (1924).

^b This unsaturated compound may be isolated in a 15% yield when the commercial mixed dimethylacetophenones are condensed with benzil; it is interesting to note that it separates without traces of any other isomers.

^c Insol. in chloroform, and recrystallized from acetic acid, in which it is slightly soluble.

^d Mixed melting point, 148–150°.

^e For the preparation of this ketone and the 2-chloro-5-methyl isomer we are indebted to Mr. M. P. Bridgess.

The condensation is not brought about by the use of pyridine, piperidine, nor a trace of sodium methylate. Two g. of potassium hydroxide in 3 cc. of water and 25 cc. of methyl alcohol may be used, however, but the product is not of as good quality.

B. The Formation of the 4-Bromofuranes.—The unsaturated diketones readily form bromofuranes when solutions in glacial acetic acid or chloroform are treated with hydrogen bromide. The procedure is to dissolve 5 g. in 20 cc. of warm acetic acid and saturate the solution by

passing through a rapid current of dry hydrogen bromide gas. In some instances the bromofuranes separate almost immediately but always after standing overnight. They all form a white, bulky precipitate of needles that felt together on filtration, and show practically the same properties except melting point. Purification is best effected by dissolving in the minimum amount of hot chloroform and adding an equal volume of alcohol. The yields are practically quantitative.

TABLE II
2,3,5-TRIPHENYL-4-BROMOFURANE AND HOMOLOGS

No.	Group in position 5	M. p., °C.	Formula	Analyses			
				Calcd., C	% H	Found, C	% H
III	Phenyl ^a	129	C ₂₁ H ₁₅ OBr				
XI	4-Methyl-	134	C ₂₂ H ₁₇ OBr	71.0	4.4	70.8	4.5
XII	3,4-Dimethyl-	137	C ₂₄ H ₁₉ OBr	71.5	4.7	71.6	4.9
XIII	4-Methoxy-	151	C ₂₃ H ₁₇ O ₂ Br	68.1	4.2	67.9	4.2
XIV	4-Chloro- ^b	127	C ₂₂ H ₁₄ OCIBr	64.4	3.4	64.1	3.2
XV	4-Chloro-3-methyl-	135	C ₂₃ H ₁₆ OCIBr	65.4	3.8	65.4	3.9
XVI	4-Bromo- ^b	157	C ₂₂ H ₁₄ OBr ₂	58.1	3.1	58.0	3.1

^a This bromofurane has been prepared once previously by the action of heat on two stereoisomeric γ -bromo- γ -nitro ketones. E. P. Kohler, private communication.

^b Dissolved in 50 cc. of acetic acid.

The bromofuranes are very sparingly soluble in the alcohols, but dissolve readily in warm ether, chloroform, benzene and glacial acetic acid. They do not reduce permanganate in acetone solution nor decolorize bromine. The bromine atom is not affected by prolonged boiling with alkalis; bromide ion cannot be detected after twenty hours of heating with alcoholic potash. It does not react with magnesium to form a Grignard reagent, a result not unexpected, since the bromine atom is *di-ortho* substituted.

This work has been assisted by a generous grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences.

Summary

1. Benzil readily condenses with acetophenones substituted in the *meta* or *para* positions in the presence of an equivalent of sodium methylate to form derivatives of phenyldibenzoyl ethylene.

2. These substances react with hydrogen bromide in such a way that the product formed is a 4-bromofurane. The bromine atom in the latter substance is inactive.

SILICON TETRACHLORIDE AS A REAGENT FOR THE PREPARATION OF ACID CHLORIDES^{1,2}

BY RALPH E. MONTONNA

RECEIVED JULY 13, 1927

PUBLISHED AUGUST 5, 1927

The action of silicon tetrachloride on organic acids has hitherto been but slightly investigated. Taurke³ obtained benzoyl chloride from benzoic acid by means of this reagent and Rauter⁴ prepared butyryl chloride by heating butyric acid with silicon tetrachloride in a sealed tube at 150–160°. These apparently constitute the only references in the literature.

In view of the author's previous success in the semi-industrial manufacture of acetyl chloride from acetic acid by this reagent (silicon tetrachloride), its action on other organic acids was investigated with a view to the preparation of a number of acid chlorides free from sulfur and phosphorus impurities.

The method followed was to dissolve the acid in an inert solvent (benzene, toluene, xylene, chloroform, etc.) and after raising the temperature to about 50° to run in the silicon tetrachloride. The acid chloride was distilled off through a fractionating column.

The mechanism of the reaction probably consists in the primary formation of a mixed anhydride of silicic and the organic acid,⁵ $4\text{RCOOH} + \text{SiCl}_4 = \text{Si(OCOR)}_4 + 4\text{HCl}$, and the secondary interaction of this with a further molecule of silicon tetrachloride, $\text{Si(OCOR)}_4 + \text{SiCl}_4 = 4\text{RCOCl} + 2\text{SiO}_2$. The following acids were investigated: acetic, propionic, butyric, isobutyric, benzoic, phenylacetic and sebacic, the yields obtained being 85, 50, 49, 51, 77, 61 and 37 per cent., respectively.

Other dibasic acids, *o*-nitrobenzoic and pyruvic acids were experimented with but negative results were obtained in all cases.

Experimental Part

Preparation of Acetyl Chloride.—Three hundred and sixty g. (six moles) of glacial acetic acid and 672 g. (six moles) of toluene are placed in a liter, round-bottomed, Pyrex flask fitted with a rubber stopper through which passed a dropping funnel and a reflux condenser. The upper portion of the latter is filled with glass beads and the condenser itself is, in turn, connected to an absorption system consisting of two wash-bottles containing acetic acid. The mixture is heated to 50° and at that temperature

¹ This paper is constructed from Part II of a dissertation presented by Ralph E. Montonna in June, 1924, to the Faculty of the Graduate School of Yale University in candidacy for the degree of Doctor of Philosophy. The investigation was carried out in the laboratory of Dr. Harold Hibbert.

² Communicated to the Organic Division, American Chemical Society, Washington, D. C., April, 1924.

⁴ Rauter, *Ann.*, **270**, 260 (1892).

⁵ Friedel and Ladenburg, *Ann.*, **145**, 174 (1868).

510 g. (three moles) of silicon tetrachloride is added from the dropping funnel during a period of 30 minutes. The same temperature is maintained until the vigorous evolution of hydrochloric acid almost ceases. The upright condenser is then replaced by a Glinsky or Hempel column carrying a thermometer and attached to a downward condenser, and the product fractionated over a free flame until the thermometer registers 80–85°. The product on redistillation gives 400 g. of acetyl chloride, b. p., 50–55°; yield, 85%.

The same method was applied to the other acids, the only difference being the use of other diluting media and a somewhat higher temperature, prior to fractionation, to ensure the completeness of the reaction.

The results obtained are tabulated below.

TABLE I
SUMMARY OF RESULTS

Exp. no.	Acid used,		Solvent	g.	SiCl ₄ , g.	Temp., °C.	Acid chloride recovered

Synthesis of Acetic Anhydride

The same reagent (silicon tetrachloride) can also be used for the preparation of acid anhydrides from the sodium salts of the corresponding acid using a diluent, preferably the anhydride itself.

In the following experiment acetic anhydride itself was used as diluent. 130 g. of anhydrous sodium acetate and 300 g. of 99% acetic anhydride were warmed to 50° and, while stirring, 67 g. of silicon tetrachloride was added during a period of one hour. The temperature rose to 80° and the heating was continued for three hours at 90°. The yield was 75% of 96% anhydride.

A second experiment carried out in glassware, using benzene as diluent and heating for five hours at 50–60°, gave a yield of 50%.

Summary

A laboratory method is described for the preparation of "phosphorus-

This is a difficult task. The quantum theory still contains so many uncertainties that a convincing elementary exposition is not yet possible, and one hundred pages is too short for any serious contribution to the extensive field that the author covers. The book, however, fulfils the author's own intention of giving a rapid survey of the whole field and contains references to a very considerable number of original contributions.

RICHARD C. TOLMAN

Die Verwendung der Röntgenstrahlen in Chemie und Technik. Ein Hilfsbuch für Chemiker und Ingenieure. (The Application of X-rays in Chemistry and Technology. A Reference Book for Chemists and Engineers.) By Dr. HERMANN MARK. Johann Ambrosius Barth, Salomonstrasse 18B, Leipzig, Germany, 1926. xv + 528 pp. 328 figs. 25.5×18 cm. Price, unbound, Rm. 48; bound, Rm. 50.

Among a list of great books already published on the various ramifications of x-ray science, there always seems to be a place for a new contribution, particularly if it emphasizes the new practical applications of a fundamental research tool. No one is better qualified by training, experience and personality to prepare a great treatise than Dr. Mark. His x-ray experiments have ranged from the purest physics to the most practical (but always thoroughly scientific) studies of the structure of rubber, worked metals and engineering materials; he assisted Polanyi in working out the complete interpretation of fiber structures which play so important a part in natural and manufactured materials.

The book is really magnificently painstaking, authoritative and complete. The advances which have been made in so few years since crystals were found to serve as diffraction gratings for x-rays are most picturesquely set forth by a comparison of the content of this encyclopedic book with the first edition of the pioneer book on x-rays and crystal structure by the Braggs, published scarcely more than a decade ago. The observer has the same feeling that he has in comparing side by side a modern, mountain-climbing super-locomotive with a courageous little "Dewitt Clinton."

The title of Dr. Mark's book is somewhat of a misnomer. The applications of x-rays in chemistry and industry are not set forth as present achievements and future possibilities so that an executive or research director might learn whether or not he had an x-ray problem. There is nothing which may be classed as introductory, popular or missionary about this contribution. It is distinctly a methodology, and as such leaves nothing to be desired, for it is doubtful if more solid "meat" was ever crammed into 528 pages.

The first section on the production of x-rays is certainly the most detailed and complete exposition of high-tension apparatus and x-ray tubes to be found anywhere. In some respects this is the best and most

original part of the book. The second section on the spectroscopy of x-rays shows the strong influence of Siegbahn's book, as is to be expected for this subject. The third section on crystal structure analysis with the help of x-rays follows the scheme of presentation in Ewald's great book, but of course goes far beyond upon the basis of recent developments. Mark's presentation of crystal symmetry, space groups and interpretation is the most logical and complete thus far published, although a chemist or engineer untrained in the subject would make difficult progress through the material. The fourth section on the determination of crystal grain orientation and particle size is disappointing in that it is not as thoroughly complete as might be hoped from an experimenter who has had a large hand in the development of these subjects. It will still be necessary to consult the series of original papers by Polanyi, Mark and others on fibering and deformation, for information as to mathematical interpretation. The last section on literature references and notes is interesting and valuable for those engaged in research.

The student (he must be this, rather than a reader) will often have the wish that more actual examples of analysis and application were given. This would, of course, prolong a book already voluminous, but it might have been done very advantageously at the expense of some of the spectroscopic data easily available elsewhere. The fact remains, however, that as a thorough handbook of experimental and interpretational methods to be used by relatively well-trained scientists, Dr. Mark's work has no equal, and if later editions keep the subject matter up to date (at the present rate of discovery a revision will certainly be required every year) it may well continue to dominate in the training of those who attempt to apply x-rays to problems of chemistry and industry.

GEORGE L. CLARK

Forschungen zur Kristallkunde: I. Trachten der Kristalle. (Researches in the Science of Crystals: I. The Habit of Crystals.) By H. TERTSCH, University of Vienna. Bornträger, Berlin, 1926. viii + 222 pp. 58 figs. 17 × 25 cm. Price 15 M.

This is the first of a new series of monographs on crystallography and related subjects, under the editorship of Professor Arrien Johnsen, of the University of Berlin. It comprises chapters on the domain of the work, methods of measurement, observations on influencing habit, the habit significance of forms, peculiarities of surface development, and the theory of the subject. There is a bibliography of 181 titles, practically all of German articles, although in some way two or three references to American journals have managed to creep in, and 12 papers by Gaubert in French are included.

Bringing together as it does material widely scattered through the

literature, this book serves a useful purpose. Chemists will be especially interested in the discussion of influencing habit by physical and chemical means, and in the theoretical treatment on the basis of the space-lattice arrangement of atoms or molecules in crystals.

EDGAR T. WHERRY

Die Herstellung kolloider Lösungen anorganischer Stoffe. (The Preparation of Colloidal Solutions of Inorganic Substances.) By Dr. JOSEF REITSTÖTTER. Theodor Steinkopff, Dresden and Leipzig, 1927. 62 pp. 2 figs. 25.5 × 18 cm. Price, unbound, M. 3.

The first fourteen pages are devoted to a brief discussion of methods of forming colloidal solutions, and the function of protective colloids. The methods are classified according to Svedberg's classification into dispersion and condensation methods. The rest of the book enumerates the methods which have been used to make colloidal solutions of various inorganic substances. The arrangement followed is to discuss each element and its most important compounds in the order of its occurrence in the periodic table rather than grouping together similar methods of preparation for different substances. This arrangement, the numerous references to scientific and patent literature and the adequate indexes make it convenient and valuable as a reference book.

NORMAN D SCOTT

A Handbook of Organic Analysis. Qualitative and Quantitative. By HANS THACHER CLARKE, D.Sc., F.I.C., with an introduction by J. NORMAN COLLIE, Professor of Chemistry in University College, London. Fourth edition. Longmans, Green and Company, 55 Fifth Avenue, New York City, 1926. xii + 363 pp. 23 figs. 19 × 12.5 cm. Price \$3.00.

The first edition of this excellent book appeared fifteen years ago, the present edition being the fourth. An extensive revision has been necessary owing to the progress made in the meantime in organic chemistry.

The first chapter deals with such topics as purity, general characteristics, methods for examination for the elements, determination of the approximate constitution and a tabular summary of preliminary tests. The second takes up the examination for various radicals and this is followed by a chapter on the separation of mixtures. Chapter IV (287 pages) gives classified tables of organic compounds, the members of each group being arranged according to melting point or boiling point. The characteristic behavior of each substance is indicated, that is, reactions particularly useful in identification.

Chapter V describes quantitative methods for the most important elements, followed by a chapter on the quantitative determination of certain radicals. The last chapter describes the methods for determining molecular weight, vapor density, density of liquids and optical rotation.

I believe a more thorough-going dependence on solubility relations would give a better system of analysis. I would also considerably abbreviate the section of compounds and their behavior so as to compel the student to rely more on the library. Quantitative methods might be left out entirely as we have satisfactory descriptions in organic laboratory manuals. As this is a book for beginners in analysis, it should be reduced to the smallest size possible.

ALVIN S. WHEELER

The Preparation and Analysis of Organic Compounds. By J. BERNARD COLEMAN and FRANCIS ARNALL. P. Blakiston's Son and Company, 1012 Walnut Street, Philadelphia, 1926. xvi + 352 pp. 42 figs. 22.5 × 14.5 cm. Price, \$4.00.

In 352 pages the authors have succeeded in presenting the important fields of organic chemistry laboratory work. This is done in five sections and an appendix. I. General processes dealing with the purification of compounds and the determination of physical constants. II. Directions for the preparation of 89 individual compounds arranged according to types of compounds prepared. The directions are preceded by brief statements of the theory and by the chemical equations involved. III. Qualitative analysis. The scheme involves grouping compounds in classes according to their elementary composition. The method, although much less extensive, has many points of resemblance to that of Mulliken, particularly noticeable in the group containing carbon and hydrogen (and oxygen). It is difficult to determine without actual trial if this scheme will in general take less time than the Mulliken procedure and if so whether or not this will outweigh the greater precision of the latter. IV. Ultimate analysis. V. Determination of molecular weights and the estimation of typical groups.

The book is well worth looking over, particularly by those who wish to have a limited treatment of the fields of organic laboratory work included under one cover. In general, the experiments are well chosen but the description of apparatus, particularly in the section on quantitative analysis, is in a few cases not strictly modern.

R. R. RENSHAW

Organische Molekülverbindungen. (Organic Molecular Compounds.) Second, revised edition. By Dr. PAUL PREIFFER, Professor of Chemistry at the University of Bonn. Ferdinand Enke, Stuttgart, 1927. xvii + 470 pp. 4 figs. 16.5 × 25.5 cm. Price, unbound, M. 40; bound, M. 42.20.

This edition, though considerably enlarged, follows closely the lines of the first edition. There is an introductory section setting forth the Werner coördination theory, first as applied to inorganic and then to organic molecular compounds. The second section discusses at length mixed inorganic-organic molecular compounds, classified primarily according to the inor-

ganic element whose residual affinity is involved. The third section presents the purely organic molecular compounds. There are two new chapters in this section: one on the detection, preparation and properties of purely organic molecular compounds, and another on the significance of these compounds in the theories of adsorption, solution and crystal structure. The fourth and last section discusses the mechanism of chemical reactions on the basis of molecular compounds as intermediate steps.

This book is on the one hand a valuable systematic compilation of organic molecular compounds, previously for the most part widely scattered through the voluminous literature of organic chemistry, and on the other an instructive discussion of their theoretical relationships.

ARTHUR B. LAMB

Practical Organic and Bio-Chemistry. By R. H. A. PLIMMER, D.Sc., Professor of Chemistry in the University of London. New Edition. Longmans, Green and Company, 55 Fifth Avenue, New York City, 1926. x + 568 pp. 67 figs. 25.5 × 16 cm. Price \$7.50.

In the course of several editions this work, "originally compiled as a handbook of practical work for medical students," has been enlarged to serve "as a textbook and practical book" on organic chemistry, and in this revision "additional matter has been added to the section on physiological chemistry." The formidable task of condensing the essentials of what are usually regarded as two fields of science into less than 550 pages has been accomplished by virtue of a logical arrangement of material, the detailed discussion of only those portions of organic chemistry of interest to physicians, and a clear and concise style. The direct, positive statements which serve well in the exposition of the established facts and classifications of organic chemistry are not, however, suited to the discussion of some of the newer and more controversial topics treated in the physiological section, where detailed evidence and a critical attitude are demanded. For example: "Shortage of vitamin C is associated with a sallow, muddy complexion and pseudo-rheumatic pains." (p. 507.)

The book is unusual among biochemical texts in that the symbol *PH* appears but once, and then without explanation. In general, the contributions of physical chemistry to biochemistry are given but slight attention, and the discussion of the blood as a carrier of gases is consequently inadequate. There is a chapter of seventeen pages on colloids and colloidal solutions.

The presence of the formulas of Harrington for thyroxin, and of Stewart and Tunncliffe for glutathione indicates that the present edition contains much recent material on the organic side of the subject. The directions for practical work are embodied in direct statements of fact rather than in questions to be answered by experiment.

F. F. HEYROTH

Lehrbuch der Enzyme. Chemie, Physikalische Chemie, und Biologie. (Textbook of Enzymes. Chemistry, Physical Chemistry and Biology.) By Professor CARL OPPENHEIMER with Dr. RICHARD KUHN. Georg Thieme, Leipzig, 1927. iv + 660 pp. 18 figs. 25 × 17 cm. Price, unbound, RM 33; bound, RM 36.

This is offered by the authors and publisher both as an essentially new book and as a fifth and completely rewritten edition of Oppenheimer's well-known textbook on enzymes. The main divisions of the book are: I, General chemistry of enzymes, 150 pages; II, Biology of enzymes, 54 pages; III, The hydrolases, 250 pages; IV, The desmolases, 195 pages. Of these, Sections I and II constitute the "general," and III and IV the "special" parts. Section I includes general introductory matter, the classification of enzymes, their descriptive chemistry, the influence of various factors upon enzymic activity, its physical chemistry and kinetics; Section II, the occurrence and formation of enzymes in nature and their significance in the economy of the living organism; Section III describes the esterases, carbohydrases, nucleases, amidases and proteases; Section IV, the general conceptions of oxidation-reduction enzymes, the zymases, dehydrases and catalases.

Notwithstanding the size and scope of this book, much of it gives the impression of expression of the authors' views rather than of mere compilation; but it can hardly be said that these views appear always to have been formed from an even weighing of all the evidence. The authors have evidently given much more attention to the original work which has been published in the German language than to that which has been published in English.

The book is written in the style in which one addresses advanced readers, the names of investigators appearing freely in the text, but in most cases the references to original papers are unfortunately not given, so that the book, while comprehensive and suggestive, does not serve effectively to put the reader in touch with all the more important of the original literature.

It would seem that this paucity of references must detract rather seriously from the value of a book of this size to many of its readers, but to those who are already accustomed to following the original literature of the enzymes this work will be of interest for its suggestiveness and as a summary of the views of its authors. It seems unfortunate that these writers should adopt so dogmatically and emphasize so often the view that Willstätter's purified enzyme preparations contained neither protein nor carbohydrate, when a study of the actual experimental evidence of Willstätter's and other investigations bearing upon the question would have shown them that no such general negative is proved. The authors' views upon the recent physical chemistry of the enzymes are well summarized in this work.

AZIDO-DITHIOCARBONIC ACID IV. AMMONIUM AND TETRAMETHYLAMMONIUM AZIDO-DITHIOCARBONATES; TETRAMETHYLAMMONIUM THIOCYANATE^{1,2}

BY L. F. AUDRIETH, G. B. L. SMITH AND A. W. BROWNE

WITH MICROSCOPICAL STUDIES BY C. W. MASON

RECEIVED DECEMBER 23, 1926

PUBLISHED SEPTEMBER 2, 1927

In view of the peculiar photosensitivity of the rubidium and cesium azido-dithiocarbonates,^{1c} it has been thought probable that the tetramethylammonium salt might, like these compounds, show a reversible color change under the influence of light. The chief objective of the present investigation has therefore been the isolation and description of this substance, which should be of interest in any event from the fact that it contains a strongly electropositive radical, or "synthetic metal" in combination with a strongly electronegative radical of the halogenoid type. For the sake of comparison, the hitherto unknown ammonium azido-dithiocarbonate has also been prepared, as well as the tetramethylammonium thiocyanate, the principal product of the thermal decomposition of tetramethylammonium azido-dithiocarbonate.

¹ For the earlier articles of this series see (a) Smith and Wilcoxon with Browne, *THIS JOURNAL*, **45**, 2604 (1923); (b) Browne and Smith, *ibid.*, **47**, 2698 (1925); (c) Browne and Audrieth, *ibid.*, **49**, 917 (1927).

² The investigation upon which this article is based was supported by a grant from the Heckscher Foundation for the Advancement of Research, established by August Heckscher at Cornell University. The present paper is Article 3 under Heckscher Grant No. 60. For Articles 1 and 2, see (a) *THIS JOURNAL*, **45**, 2604 (1923); (b) **47**, 1916 (1925). For articles 1, 2, 3 and 4 under Heckscher Grant No. 4, see (c) *ibid.*, **44**, 2106 (1922); (d) **44**, 2116 (1922); (e) **44**, 2315 (1922); (f) **45**, 2541 (1923).

Ammonium Azido-dithiocarbonate³

This compound may be obtained (1) by neutralization of free azido-dithiocarb acid^{1a} with ammonium hydroxide in aqueous solution, (2) by prolonged treatment of ammonium trinitride in aqueous solution with carbon disulfide under conditions prescribed for use in the synthesis of the potassium salt,^{2b} and (3) by bubbling ammonia gas through an ethereal solution of the azido-acid. The third procedure, which is similar to the method used by Browne and Houlehan⁴ in preparing ammonium trinitride, was adjudged the most satisfactory for the present investigation.

The ammonium radical was determined in the usual way after distillation of the ammonia from alkaline solution into standard sulfuric acid. The azido-dithiocarbonate radical was determined by the modified Volhard method recommended by Browne and Smith.^{1b}

Anal. (a) Subs., 0.6584, 0.7965: NH_4 , 0.0864, 0.1063. Calcd. for NH_4SCSN_3 : NH_4 , 13.25. Found: 13.12, 13.35. (b) Subs., 0.3097, 0.1783: SCSN_3 , 0.2694, 0.1505. Calcd. for NH_4SCSN_3 : SCSN_3 , 86.8. Found: 87.0, 86.8.

Ammonium azido-dithiocarbonate is a white, crystalline, non-deliquescent solid, readily soluble in water, methyl or ethyl alcohol, and acetone, somewhat soluble in ether, but practically insoluble in benzene and xylene.

Heated in a Thiele melting-point tube the ammonium salt assumes at 90° a reddish-orange color, RO-O on the Milton Bradley Standard.⁵ Decomposition becomes perceptible at about 110°, and the substance melts with evolution of gas at about 120°. The residue was found to consist of ammonium thiocyanate and sulfur, indicating that the reaction proceeds in accordance with the equation $\text{NH}_4\text{SCSN}_3 = \text{NH}_4\text{SCN} + \text{S} + \text{N}_2$. Larger samples have been found to decompose suddenly, with a puff, between 115 and 120°.

Samples composed of larger crystals obtained by the second method were invariably found to decrepitate vigorously between 80 and 100° as a result of the presence of occluded nitrogen formed during prior thermal decomposition. When such crystals are dissolved in water the presence of these occluded gases becomes manifest.

On exposure to direct sunlight the salt undergoes coloration, within a few minutes, to a very light orange tint, OT2 on the Milton Bradley Standard.⁵ A partial reversal of this color change takes place very slowly in the dark.

When strongly heated on an asbestos board, the salt suddenly decomposes with considerable flame and a puff of smoke. An attempt to effect a molecular rearrangement of the salt by heating a sample in a sealed tube resulted in a violent explosion.

Under the microscope, ammonium azido-dithiocarbonate is seen to form crystals that are mostly thick, six-sided tablets of varying proportions. The parallel or symmetrical extinction exhibited in more than one position, together with the crystal forms present, indicate that the substance very probably is orthorhombic. The terminal angle of the truncated rhomb-shaped crystals is about 120°. Numerous forms are represented on well-developed crystals: 001, 100, 010, 111, 211, 110, and probably other forms as well, may be recognized. The index of refraction is about 1.9 for vibrations

³ The authors would express, herewith, their appreciation of the assistance rendered by Mr. G. G. Parker, of this Laboratory, in connection with a part of the experimental work upon this substance.

⁴ Browne and Houlehan, *THIS JOURNAL*, 33, 1742 (1911).

⁵ Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, New York, 1st ed., 1905, Vol. I, p. 232.

parallel, and 1.7+ for vibrations perpendicular, to the long diagonal of the rhomb-shaped forms. Double refraction is strong; the interference figure is biaxial, but the axial angle is so large that the acute bisectrix and the sign of double refraction cannot be determined with certainty. The axial plane is parallel to the short diagonal of the rhomb-shaped forms.

Tetramethylammonium Azido-dithiocarbonate $N(CH_3)_4SCSN_3$

Three methods for the preparation of this substance have been studied: (1) neutralization of free azido-dithiocarbonic acid with tetramethylammonium hydroxide in aqueous solution, (2) double decomposition of barium azido-dithiocarbonate and tetramethylammonium sulfate, and (3) digestion of an aqueous solution of tetramethylammonium trinitride, a compound first prepared in this Laboratory by Friedlander,⁶ with an amount of carbon disulfide slightly in excess of that required by the equation $N(CH_3)_4N_3 + CS_2 = N(CH_3)_4SCSN_3$. The third method, carried out under the conditions specified by Browne and Hoel,²⁰ was found most satisfactory for use in the current investigation.

Nitrogen was determined by the Dumas method, and the azido-dithiocarbonate radical by the modified Volhard procedure.^{1b}

Anal. (a) Subs., 0.1164, 0.1054: N_2 (corr.), 26.9, 24.2 cc. Calcd. for $N(CH_3)_4SCSN_3$: N_2 , 29.1. Found: 28.9, 28.7. (b) Subs., 0.2217, 0.2220: $SCSN_3$, 0.1362, 0.1360. Calcd. for $N(CH_3)_4SCSN_3$: $SCSN_3$, 61.5. Found: 61.4, 61.3.

The tetramethylammonium salt crystallizes from aqueous solution in the form of large, white tablets, which may be purified by recrystallization from warm alcohol. The addition of ether to an alcoholic solution results in the precipitation of the salt in a voluminous, finely divided mass. The compound is readily soluble in water, fairly soluble in either methyl alcohol or acetone, slightly soluble in ether, and insoluble in carbon tetrachloride, carbon disulfide and chloroform.

The salt does not explode when struck with a hammer. When thrown upon the hot plate, or heated directly in the Bunsen flame, it suddenly decomposes with a puff. Heated gently, the substance always yields the characteristic odor of trimethylamine, which indicates that the primary decomposition of the substance may involve its dissociation into the tertiary amine and methyl azido-dithiocarbonate, in accordance with the equation $N(CH_3)_4SCSN_3 = N(CH_3)_3 + CH_3SCSN_3$.

In the melting-point tube the substance apparently undergoes fusion at 95–98°, assuming at the same time a dark green color. The color change is usually followed by a sudden puff indicative of complete decomposition. Like all other azido-dithiocarbonates thus far studied the tetramethylammonium salt gradually decomposes, even at room temperature, with formation of the thiocyanate, sulfur and nitrogen. In aqueous solution the negative ion resists decomposition for a time, and only after several hours of vigorous boiling fails to respond to the usual qualitative tests.

On exposure at room temperature to direct sunlight the white salt in a few minutes assumes a light orange color, OT1 on the Milton Bradley Standard.⁵ In the dark this effect undergoes a gradual reversal which takes place more slowly than in the case of the cesium salt.¹⁶ Further work on the photosensitivity of the tetramethylammonium salt and of various other azido-dithiocarbonates and related compounds is now in progress.

Under the microscope the salt is seen to crystallize from aqueous solution in the form of rectangular tablets and stout prisms with beveled long edges. Some crystals show parallel extinction and give biaxial interference figures. They are optically positive, with 2V rather small, the axial plane being parallel to the elongation of the tablets, and

⁶ Friedlander, *THIS JOURNAL*, 40, 1945 (1918).

the acute bisectrix perpendicular to their principal plane. Other crystals, lying on one of the beveling faces, give oblique dispersed extinction and somewhat anomalous polarization colors. The maximum extinction angle observed is about 40° for the position corresponding to an edge view of the elongated tablets. Some end views were observed and these showed parallel extinction. The optical properties and symmetry of the crystals point to their being in the monoclinic system.

Tetramethylammonium Thiocyanate $N(CH_3)_4SCN$

In connection with a study of the power of solution and ionization of various non-aqueous solvents towards binary salts, Walden⁷ prepared tetramethylammonium thiocyanate (1) by heating methyl thiocyanate with a solution of trimethylamine. During the current research this method has been compared with two others, by which the salt is obtainable either (2) by prolonged boiling of an aqueous solution of tetramethylammonium azido-dithiocarbonate, until quantitative decomposition into the thiocyanate has occurred, or (3) by bringing together tetramethylammonium trinitride⁸ and carbon disulfide in alcoholic solution and boiling under the reflux condenser until the reaction has proceeded to completion.⁸ The third method was found most convenient. Four cc. of carbon disulfide was dissolved in 50 cc. of absolute alcohol, and 5 g. of tetramethylammonium trinitride was added little by little to the boiling solution, which was refluxed until qualitative tests indicated the absence of trinitrides and azido-dithiocarbonates. After the solution had been concentrated and cooled, the thiocyanate was recrystallized from alcohol and obtained in the form of glistening white needles.

Nitrogen was determined by the Dumas method, and thiocyanogen was weighed as the silver salt.

Anal. (a) Subs., 0.1654, 0.1787: N_2 (corr.), 28.23, 30.45 cc. Calcd. for $N(CH_3)_4SCN$, N_2 , 21.2. Found: 21.35, 21.32. (b) Subs., 0.1933, 0.1847: $AgSCN$, 0.2413, 0.2310. Calcd. for $N(CH_3)_4SCN$: SCN , 43.9. Found: 43.7, 43.8.

Tetramethylammonium thiocyanate is fairly soluble in water and methyl alcohol, slightly soluble in ethyl alcohol and acetone, and insoluble in ether, chloroform, carbon disulfide and carbon tetrachloride.

When heated in the melting-point tube, the substance volatilizes at $304\text{--}305^\circ$. From the odor it is apparent that thermal dissociation into the tertiary amine and methyl thiocyanate readily takes place. By dry distillation a yellowish oil which boils at 132° (b. p. of CH_3SCN , 133°) is obtained.

Under the microscope the salt crystallizes in rectangular prisms with the long edges beveled, and in tabular crystals (flattened prisms). A few end views were obtainable, and these corresponded to the prismatic forms in symmetry and optical properties. The crystals exhibit parallel extinction in all positions, with moderately strong birefringence. They are biaxial, optically positive, with $2V$ rather small. The plane of the optic axis is parallel to the elongation of the tabular forms, and the acute bisectrix is perpendicular to their principal plane. The symmetry and optical properties indicate that the crystals are in the orthorhombic system.

Tetramethylammonium thiocyanate is empirically isomeric, not only with tetramethyl thio-urea,⁹ but also with numerous other derivatives

⁷ Walden, *Z. Elektrochem.*, **27**, 34 (1921).

⁸ Stollé [*Ber.*, **55**, 1289 (1922)] has shown that sodium trinitride and carbon disulfide react in boiling alcoholic solution to form sodium thiocyanate, free sulfur and nitrogen gas. The fact that sodium azido-dithiocarbonate was undoubtedly formed as an intermediate product seems to have escaped the notice of this investigator.

⁹ Billeter, *Ber.*, **43**, 1853 (1910).

of thio-urea, including the *sym.*-diethyl,¹⁰ *isobutyl*,¹¹ *sym.*-butyl,¹² normal butyl,¹³ *d-sym.*-butyl,¹³ methyl *sym.*-propyl,¹⁴ α, α' -dimethyl- β -ethyl,¹⁵ and *unsym.*-diethyl¹⁶ thio-ureas. In the thought that the tetramethylammonium salt might undergo transformation into tetramethyl thio-urea, several preliminary experiments have been performed. No evidence of such a molecular rearrangement has thus far been obtained.

Summary

Two new compounds, ammonium azido-dithiocarbonate, NH_4SCSN_3 , and tetramethylammonium azido-dithiocarbonate, $\text{N}(\text{CH}_3)_4\text{SCSN}_3$, have been prepared and described. Both are white, crystalline solids, fairly stable at room temperature, but decomposing rapidly, and under certain conditions explosively, when heated. Both undergo a curious color change; the former when either heated or illuminated, the latter when illuminated at ordinary temperature.

Tetramethylammonium thiocyanate, a product of the thermal decomposition of the tetramethylammonium azido salt, has also been prepared and studied.

THE VOLUMETRIC DETERMINATION OF HYDRAZOIC ACID BY OXIDATION WITH CERIC SULFATE IN ACID SOLUTION

By JEROME MARTIN

RECEIVED MARCH 3, 1927

PUBLISHED SEPTEMBER 2, 1927

Sommer and Pincas¹ developed a nitrometric method for determining hydrazoic acid which depends on its oxidation by a ceric salt in acid solution, and showed that the nitrogen evolved corresponds to the reaction $2\text{Ce}^{++++} + 2\text{HN}_3 = 3\text{N}_2 + 2\text{Ce}^{+++} + 2\text{H}^+$. In the present investigation an iodimetric method based on this reaction has been found to give satisfactory results. A measured quantity of a stock solution of ceric sulfate is added and the excess is determined iodimetrically. The writer is not aware of any other titration method which depends on the oxidation of hydrazoic acid.²

Preparation of Solutions

The hydrazoic acid used in this work was prepared by the method of Browne.³ From this a stock solution of sodium azide was made by neutralization with sodium hydroxide. This stock solution was standardized by the gravimetric method of Turrentine and Olin,⁴ and the average value of five determinations was $0.1097 \pm 0.1\%$.

Two different stock solutions of ceric sulfate were prepared and standardized iodimetrically.⁵ Solution A was prepared by the electrolysis of cerous sulfate in 6 *N* sulfuric acid. Solution B was obtained by diluting with water a paste of ceric oxide and concd. sulfuric acid until the acid concentration was 2 *N*. The latter method is preferable since it is easier to carry out.

The thiosulfate solution was standardized against known potassium permanganate solution⁶ which had been standardized against Bureau of Standards sodium oxalate.

The Standard Procedure is as follows. The air in a ground-glass stoppered flask is displaced by a current of nitrogen or carbon dioxide, and the neutral or slightly basic solution of hydrazoic acid added. A

measured excess of a standard ceric sulfate solution is quickly added, the flask stoppered, shaken vigorously, and allowed to stand for five minutes. An excess of potassium iodide is then added and the liberated iodine titrated with 0.1 *N* thiosulfate solution, using starch as an indicator. A solution of 0.01 *N* iodine may be used to determine the end-point more exactly.

The experimental results are shown in Table I.

Discussion of Experimental Results

Expts. 1-4 in which Solution A was used cannot be given much weight since the high acid concentration would accentuate the oxygen error, due to a trace of residual oxygen, either in the standard procedure or in the standardization of the stock ceric sulfate solution.

The reaction is complete in five minutes under the conditions employed, but Expts. 10, 11 and 14 show that it is not complete in one minute.

That the excess of ceric salt does not affect the results is shown by comparing Expts. 12-13 with Expts. 5-9. This indicates that the reaction is smooth, and free from side reactions.

That ammonium ion has no effect on the ceric ion-hydrazoic acid reaction is shown by Expts. 15 and 16 which differed from the standard procedure only in that 5 g. of ammonium sulfate was dissolved in the solution of sodium azide before the ceric sulfate was added. Additional experiments showed that ammonium ion is slowly oxidized at boiling temperature when the acid concentration is high (about 20 *N*), but not under other conditions.

The method cannot be used in the presence of hydrazine since it is oxidized rapidly by ceric salt, the products being nitrogen and ammonium ion. More nitrogen is evolved than corresponds to the equation,⁷ $2\text{Ce}^{++++} + 2\text{N}_2\text{H}_4 = \text{N}_2 + 2\text{NH}_4^+ + 2\text{Ce}^{+++} + 2\text{H}^+$. However, the hydrazoic acid can be distilled from the acid solution of hydrazine.

The two sources of error are the volatility of the hydrazoic acid in acid solution, and the catalytic effect which cerous ion exerts on the oxygen-iodide reaction. When the acid concentration is low, the latter error may be rendered negligible by using oxygen-free water and sweeping out the reaction flask with nitrogen. The effect of the volatility of the hydrazoic acid was reduced by adding the ceric sulfate quickly, stoppering the flask and shaking vigorously.

The author wishes to thank Professor William C. Bray for his suggestions and interest in this work.

Summary

Hydrazoic acid has been determined volumetrically by a method which depends upon the oxidation of hydrazoic acid to nitrogen by ceric sulfate

⁷ Benrath and Ruland, *Z. anorg. Chem.*, 114, 287 (1920).

in acid solution. The method is accurate to within 0.1% if care is taken to eliminate the oxygen-iodide error and if the loss of hydrazoic acid by volatilization is prevented. Hydrazoic acid cannot be determined in the presence of hydrazine, but the two can be readily separated. Ammonium ion has no effect on the method.

THE ADSORPTION OF HYDROGEN AND ETHYLENE ON A COPPER CATALYST POISONED WITH CARBON MONOXIDE

BY CARROLL W. GRIFFIN

RECEIVED MARCH 21, 1927

PUBLISHED SEPTEMBER 2, 1927

Some years ago Taylor and Burns¹ in studying the adsorption of gases on metallic catalysts found that catalytically active copper adsorbed ethylene strongly at low temperatures and hydrogen less strongly. Later Pease² took up the study of the hydrogenation of ethylene using copper as the catalyst. He pointed out the apparent correlation of catalytic activity and strong or low-pressure adsorption of reactants in view of the fact that either mercury poisoning or heat treatment of the copper caused a simultaneous and marked decrease of both of these properties. This was followed by a study by Pease and Stewart³ of the effect of carbon monoxide as a poison to the reaction. They showed that less than 0.05 cc. of carbon monoxide reduced by 88% the activity (towards an ethylene-hydrogen mixture) of a copper catalyst which adsorbed at less than one mm. pressure approximately 1 cc. of hydrogen, 2 cc. of ethylene or 5 cc. of carbon monoxide. Their conclusion was that the copper surface owed 88% of its catalytic activity to less than 1% of the centers active in adsorption, thus emphasizing the existence on the copper surface of centers of different degrees of activity. The adsorption of the reactants on the catalyst poisoned with carbon monoxide had not been measured and it was suggested to the writer by Dr. R. N. Pease that such measurements be made.

Procedure

The apparatus, the method of preparation of the catalyst, of the hydrogen and of the ethylene, as well as the taking of measurements and the limit of accuracy, were as Pease⁴ has previously described. Pure carbon monoxide was obtained by the decomposition of formic acid and passage of the gas over phosphorus pentoxide and soda lime. The 63.42 grams

⁴ Pease, *Refs.* 2 and 3.

of copper used was the second catalyst employed by Pease and Griffin⁵ and thus already established as permanently active to a high degree. The poison, carbon monoxide, was always introduced into the catalyst bulb approximately a half hour before a run was started. At the end of the run pumping out at 200° completely removed the hydrogen or ethylene and also the poison. Measurements were made at 20 and at 0°. Helium, assumed unadsorbed, was used as a reference gas.

Curve 1, H_2 with no CO; 2, H_2 with 0.038 cc. CO; 3, H_2 with 0.26 cc. CO; 4, H_2 with 0.74 cc. CO; 5, C_2H_4 with no CO; 6, C_2H_4 with 0.038 cc. CO; 7, C_2H_4 with 0.24 cc. CO; 8, C_2H_4 with 0.73 cc. CO; 9, pure CO.

Fig. 1.—Adsorptions of hydrogen and ethylene on copper poisoned with carbon monoxide at 0°. Weight of copper catalyst: 63.42 g. Volume of dead space: 22.35 cc.

Adsorptions of the three gases on the pure catalyst were made first. Then hydrogen adsorption was alternated with ethylene on the catalyst poisoned first with 0.038 cc. of carbon monoxide and then with about 0.75 cc. and finally with about 0.25 cc. A run at 20° was always followed by the corresponding run at 0°.

Constancy of Activity.—Reaction velocity runs with 1:1 mixtures of ethylene and hydrogen were used as checks on the activity of the catalyst.

⁵ Pease and Griffin, *THIS JOURNAL*, 49, 25 (1927).

The first was made at the beginning of the investigation, another midway, and a third at the end of the research. Taking the activity of the first as 100%, the second proved to be 104% (based on the time required for the pressure to drop from 700 mm. to 600 mm.) and the third 108%. Due to the fact that the reaction velocity was very rapid (being practically completed in 7 minutes) these are considered as very satisfactory checks.

About a week after all the runs were completed a small crack occurred in the catalyst bulb, which allowed a very slight oxidation of the copper

Curve 1, H_2 with 0.76 cc CO; 2, H_2 with 0.27 cc. CO; 3, H_2 with no CO; 4, H_2 with 0.038 cc. CO; 5, pure CO.

Fig. 2.—Adsorption of hydrogen on copper poisoned with carbon monoxide at 20° . Weight of copper catalyst: 63.42 g. Volume of dead space: 22.35 cc.

to take place. The crack was sealed and a new helium run was made. A subsequent reaction velocity run showed a less active catalyst, 64%, and an ethylene adsorption run at 20° following this showed an adsorption practically unchanged up to one-half atmosphere and only 7.8% less at one atmosphere. This confirmed the belief that reaction velocity is a more sensitive test of surface condition than adsorption, and that during the course of the investigation the catalyst remained substantially constant in both its catalytic and adsorptive activity.

Following experiments with this sample of copper, another sample

was used with which five runs were made. The first and last were ethylene runs on the pure sample, poisoned runs intervening. The adsorption activity was identical in the first and fifth runs.

It is noteworthy that throughout the first several runs, in addition to measurements made as gas was admitted to the catalyst bulb, portions of gas were withdrawn and readings taken. The points so secured fall on the curves with the same accuracy as those obtained when the gas was admitted, thus showing the absence of hysteresis.

Curve 1, C_2H_4 with no CO; 2, C_2H_4 with 0.24 cc. CO; 3, C_2H_4 with 0.72 cc. CO.

Fig. 3.—Adsorption of ethylene on copper poisoned with carbon monoxide at 20° . Weight of copper catalyst: 63.42 g. Volume of dead space: 22.35 cc.

Results.—Adsorption isotherms at 0° are shown in Fig. 1. On the unpoisoned catalyst these are essentially the same as obtained by Pease. Curves 2, 3 and 4 for hydrogen and 6, 7 and 8 for ethylene show the effect of poisoning with progressively greater amounts of carbon monoxide. Considering for the moment higher pressures, it is noticed that both in the case of ethylene and hydrogen the effect of the poison is a progressive decrease of adsorption with increase of carbon monoxide. In the isotherms at 20° (shown for hydrogen in Fig. 2 and for ethylene in Fig. 3) at pressures of about a half to one atmosphere the same result is

found. In Figs. 2 and 3 it is seen that at lower pressures there is an *increase* of adsorption where poison was used. This increase diminishes as the pressure increases, the curve crossing the isotherm of the gas on the unpoisoned copper and representing thereafter a *decrease* in adsorption for the higher pressures. This increase of adsorption persists, in general, to higher pressures for hydrogen than for ethylene, and for either gas the smallest amount of poison causes the greatest increase of adsorption at low pressures and the least decrease of adsorption at high pressures.

Curve 2, H_2 with 0.038 cc. CO; 3, H_2 with 0.26 cc. CO; 4, H_2 with 0.74 cc. CO; 6, C_2H_4 with 0.038 cc. CO; 7, C_2H_4 with 0.24 cc. CO; 8, C_2H_4 with 0.73 cc. CO.

Fig. 4.—Effect of poison on adsorption at 0°.

With one exception the same kind of behavior is found in the 0° curves, but in some cases the points at which the poison curves cross the unpoisoned isotherms are at such low pressures as probably not to be at once evident in Fig. 1. To bring out these considerations more distinctly, Figs. 4 and 5 are drawn in which pressure is plotted against $V_1 - V_2$, where V_1 is the volume of the gas adsorbed by the poisoned catalyst and V_2 is the volume of the gas adsorbed by the pure catalyst. The exception referred to above is the case of ethylene at 20° with 0.72 cc. of carbon monoxide as poison. Here at the lowest pressure measured there is already a decrease in adsorption due to the poison. By extrapolation,

however, it is evident that here also at very low pressure there is an increase over normal adsorption.

It will be noted that no curve is given for ethylene at 20° with 0.038 cc. of poison. Such a run was made; however, it was found to show a decrease in adsorption considerably greater than the run in which even 0.72 cc. of carbon monoxide had been used. Since such a result is not compatible with the research as a whole, it is believed that some unknown source of error entered this run. As calculations were not made until practically all the runs had been completed, this incongruity was not noticed until after the catalyst was no longer available. A new sample

Curve 1, H₂ with 0.038 cc. CO; 2, H₂ with 0.27 cc. CO; 3, H₂ with 0.76 cc. CO; 4, C₂H₄ with 0.24 cc. CO; 5, C₂H₄ with 0.72 cc. CO, broken line, C₂H₄ with 0.038 cc. CO (new catalyst).

Fig. 5.—Effect of poison on adsorption at 20°.

of copper oxide was later reduced and five runs made on the copper (125 g.) including a run of ethylene on the pure copper followed by a carbon monoxide run and then ethylene on the catalyst poisoned first with 0.038 cc. of carbon monoxide and then with 0.24 cc. The 0.038 cc. poison run showed a low-pressure increase of adsorption and a high-pressure decrease; the decrease, however, as had been expected, was less than that caused by 0.24 cc. of poison on the same catalyst. In Fig. 5 the effect of the 0.038 cc. of carbon monoxide on this new catalyst is shown by the broken curve. (This broken curve is the only one from the new catalyst. All other curves refer to the original catalyst.)

A reaction velocity measurement with a 1:1 mixture of ethylene and

hydrogen on the catalyst poisoned with 0.038 cc. carbon monoxide showed a decrease in catalytic activity of 80%, a fair check with the result of 88% obtained by Pease and Stewart⁴ with their catalyst.

Discussion of Results

The fact that the results of this work show as an effect of carbon monoxide poisoning an increase of low-pressure adsorption of hydrogen and ethylene is precisely the opposite of what was expected in view of the results of previous workers. Rather, it had been believed that isotherms similar to those found where mercury had been used as a poison or where the copper had been treated with heat would be obtained. It was even as great a surprise to find, whatever the effect, that it should be reversed at higher pressure.

Doubtless there are more ways than one of viewing these results. The low-pressure increase of adsorption due to the poison is quite definite, and even in those cases where the increase is only very slight and possibly within the magnitude of the experimental error, it is believed that they are nevertheless real and significant in view of the fact that without exception every run exhibited the low-pressure increase.

It is conceivable that the carbon monoxide simply caused a redistribution of adsorptive power among the active centers, altering the adsorption at various pressures without changing the number of centers and thus without changing appreciably the total, eventual adsorption at an indefinitely higher pressure. It hardly seems, however, that such reasoning could explain the results obtained, for it would then be difficult at least to explain a decrease of adsorption greater than the amount of poison added.

Inasmuch as the critical temperature of hydrogen is very low, namely, -234.5° , and qualitatively hydrogen and ethylene behave alike in their adsorption on the poisoned catalyst, it is evident that capillary condensation does not take place and thus any peculiar effect of the poison on that process is presumably out of the question.

Therefore, it seems necessary to assume that an adsorbed carbon monoxide molecule is capable of linking several hydrogen or ethylene molecules, perhaps to itself, perhaps by increasing the activity of neighboring centers, or possibly both. If this is true then the results may be looked upon as follows. The carbon monoxide must be adsorbed on the very active centers in view of the marked decrease in catalytic activity caused by an extremely small amount of poison. The carbon monoxide thereafter takes up hydrogen or ethylene molecules to such an extent that the total adsorption at a given low pressure is greater than on the unpoisoned catalyst where each very active point presumably holds only one molecule. This could explain that part of the curve showing an increase of adsorption.

It is difficult to say why an increase of adsorption should at higher pressure give way to a decrease. The accumulation of more and more data on the subject of adsorption seems to indicate that the process probably is complex, involving not simply one kind of action but nearly always several agencies, all included under the term sorption. It may be true that in the case of ethylene and hydrogen on copper, the measurements made have not been a record of adsorption, pure and simple. In the case in hand, possibly in addition to adsorption of the gases on the surface, actual solution of the gases is involved. If solution actually did take place it might indicate the presence of more or less amorphous copper. Rideal⁶ assumes the presence of the amorphous form in such samples as have been employed by Pease; he even supposes the strongest catalytically active centers of copper to be amorphous "patches."

It is true that Sieverts'⁷ studies do not indicate solution of hydrogen in copper at the temperatures of 20 and 0°. However, Sieverts used electrolytic copper wire, whereas that employed in this research was obtained by slow reduction of copper oxide at 150°.

Assuming a secondary action in addition to that of straight adsorption, Curve X of Fig. 6 could represent that due strictly to adsorption. Curve Z would represent the sorption actually observed on the pure catalyst and due to surface adsorption plus the secondary action. If the secondary action were that of solution it would be negligible at low pressure and thus practically coincident with Curve X in that region. One would expect the increase of surface adsorption due to the poison to continue at all pressures. If, in addition, the poison prevents the solution process, the sorption on the poisoned catalyst would be represented by Curve Y. Curves Z and Y represent what actually are found on the pure and on the poisoned catalyst, respectively, while Curves X and Y represent what might be found were the secondary action absent.

Suppose the secondary factor to be solution. If the carbon monoxide attaches little or no more hydrogen at higher pressures than at zero pressure, and were the amount dissolved unaffected, then the curves of Figs.

Volume of sorption.

Fig. 6.

⁶ Rideal, "Surface Chemistry," Cambridge University Press, 1926, p. 183.

⁷ Sieverts, *Z. physik. Chem.*, 60, 145 (1907).

4 and 5 would be horizontal lines. The vertical distances between such a line and the actual curve at a given pressure would represent the difference in the amount of gas dissolved in the pure copper and in the poisoned copper. By extrapolating the three hydrogen curves of Fig. 4 to zero pressure and arithmetically adding to these values the corresponding decrease at 700 mm. pressure, the result is roughly 0.60 cc. for the smallest amount of poison and 0.85 cc. for each of the two larger amounts. Such a relation indicates that 0.038 cc. of the poison was almost enough and 0.26 cc. or 0.74 cc. entirely sufficient to prevent solution. At 20° (Fig. 5) the hydrogen curve for 0.038 cc. of poison exhibits a relatively slight difference of solution compared to that of the unpoisoned copper, and the curves for the two larger amounts of poison show diminutions practically identical in themselves but much greater than that for the smallest quantity of poison. Comparison of hydrogen curves at 0 and 20° in Figs. 4 and 5 shows that the solubility is slightly greater at 20 than at 0°, as would be expected. With the larger amounts of poison the solubility difference between pure and poisoned copper is about 0.98 cc. at 20° as compared with 0.85 cc. at 0°. The approximately parabolic form of these curves indicates that the solubility is proportional to the square root of the pressure as Sieverts and Krumbhaar⁸ found to be the case for hydrogen in copper at higher temperatures.

That a very small quantity of poison is sufficient to prevent solution in the copper may be attributed to its ability to incapacitate the very active centers on the copper surface, thereby depriving the molecular hydrogen of its dissociating agency. The nature of the ethylene curves differs from that of hydrogen chiefly in that at 0° they bend more abruptly in approaching zero pressure. Without further hypothesizing it is, therefore, difficult to draw similar conclusions for ethylene.

It appears that a different attack on the problem presented by this investigation may be pursued, since a supported catalyst should largely do away with all except surface adsorption, and it seems that much might be learned by poisoning such a catalyst. It is planned to investigate this possibility.

Finally, it should be mentioned that it appears now more certainly than ever that adsorptions even at very low pressures do not serve as a measure of catalytic activity. Furthermore, it should be recorded that those molecules of hydrogen or ethylene which give the low-pressure increase of adsorption—that is, those molecules which owe their linkage to the poison itself, either directly or indirectly—are *not* activated. That this is definitely a fact is evidenced by the catalytic inactivity of the poisoned copper, for although in the low-pressure region the adsorption of both gases is actually increased by the poison, nevertheless the copper is practically inert as a catalyst.

⁸ Sieverts and Krumbhaar, *Z. physik. Chem.*, **74**, 277 (1910).

The writer wishes to express his heartiest thanks to Dr. A. F. Benton, whose frequent advice was of great value.

Summary

1. Adsorption measurements have been made for ethylene and hydrogen on a copper catalyst poisoned with carbon monoxide.

2. It has been found that the poison causes a low-pressure increase and a high-pressure decrease of adsorption as compared to measurements made on the unpoisoned catalyst. The poison decreases the catalytic activity very markedly.

3. A possible, general interpretation of the results has been outlined, assuming the process of sorption to comprise a secondary factor such as solution in addition to surface adsorption.

4. It has been shown that carbon monoxide in causing extra, low-pressure sorption of the gases does not leave the hydrogen or ethylene in an activated state.

THE PHOTOCHEMICAL REARRANGEMENT OF ACETYLCHLORO-AMINO BENZENE

BY C. W. PORTER AND PAUL WILBUR

RECEIVED APRIL 1, 1927

PUBLISHED SEPTEMBER 2, 1927

The photochemical rearrangement of acetylchloro-aminobenzene to *p*-chloro-acetanilide has been the subject of many investigations, but heretofore the absorption coefficients in the region of effective radiation have not been determined. A study of factors governing the rearrangement in the solid phase has not been made, although Slosson¹ long ago reported the observation that heat alone causes the change. The rearrangement in the presence of various solvents has received careful attention.²

We have undertaken to measure the energy required to convert one molecule of the chloro-amine into the isomeric form. As a preliminary step we determined the absorption coefficients of acetylchloro-aminobenzene and of the *p*-chloro-acetanilide over the range between 2200 and 3400 Ångström units. These results, with some observations relating to the rearrangement in the solid phase, are presented in this paper. The energy measurements which have been made on the absorption of certain narrow bands in the spectrum will be published after we have made further attempts to obtain results with pure monochromatic light.

The absorption coefficients were determined as follows. The spectrum

of the mercury-vapor arc was photographed through a quartz cell containing the pure solvent (conductivity water) and through copper gauze screens. On the same plate, and with equal exposures for corresponding pairs, other series of photographs were made with the screens removed and with the quartz cell filled with solutions of known concentrations of the substance under investigation. The fraction of the total incident light which passed through each screen had been determined in advance by photometric measurements in the visible region. The logarithm of the reciprocal of this ratio is the value of ecd in the statement of Beer's law, $I_t/I_0 = 10^{-ecd}$.

Points of equal degrees of blackening on two photographs on the same plate, one taken through a screen of known absorption, and the other through a solution of known concentration, c , and known depth, d , correspond to frequencies where the two systems have the same absorption coefficient, e .

2581	89	2351	114	2230	53

The points of equal densities were determined by projecting the images of the photographic negatives on a vacuum thermopile and finding positions that caused equal galvanometer deflections.³ The wave lengths corresponding to these points of equal intensities were determined by reference to known lines in the mercury spectrum. In all cases the measurements were made at temperatures between 22 and 25°. The length of the quartz cell containing the solutions was 5.25 cm. The solvent was water. The photographs were taken through a Hilger quartz prism spectrograph.

Fig. 1.

These values, together with some data obtained from several other plates, are shown in Figs. 1 and 2. Values referring to points that could not be determined within 10 Å. are, of course, only approximations.

Pure, dry crystals of acetylchloro-aminobenzene, when exposed to the radiation of a mercury-vapor lamp, are converted rapidly into *p*-chloro-

³ Ramsperger and Porter, *THIS JOURNAL*, 48, 1267 (1926).

acetanilide. A 90 per cent. conversion was made within eight hours by placing a thin layer of the crystals in an open dish at a distance of 20 cm. below a 220-volt lamp.

The same change can be induced by heat alone. The reaction is slow unless the acetylchloro-aminobenzene is heated to its melting point. Above the melting point the change is rapid, but it is not possible to maintain a constant temperature within the molten mass. The energy of the reaction causes local heating and an acceleration of rate until finally the rearrangement is completed with almost explosive rapidity.

Fig. 2.

Sealed tubes containing the crystalline solid were immersed in a water-bath at 100°. The crystals melted immediately, but within two hours the material had again become solid, due to complete conversion to the higher-melting product. No nitrogen was evolved in the process and, although slight discoloration was sometimes observed, the product was always found to be almost exclusively *p*-chloro-acetanilide.

The claim that the conversion of acetylchloro-aminobenzene into *p*-chloro-acetanilide is actually a rearrangement has been challenged under the assumption that it is a two- or three-stage process.⁴ Many

⁴ Kipping, Orton and others, *Chem. News*, 108, 155 (1913).

mechanisms involving the formation of intermediate products with the solvent or with an added catalyst have been proposed.

While these mechanisms may apply to the reaction in the specified environment, they certainly do not describe the behavior of the compound in the dry state. A direct unimolecular exchange of positions between the amino halogen and nuclear hydrogen seems to be the simplest assumption in connection with the photochemical rearrangement of the pure, dry crystals.

Summary

The ultraviolet absorption spectrum of acetylchloro-aminobenzene and of its rearrangement product, *p*-chloro-acetanilide, has been plotted.

The rearrangement is caused by heat alone at comparatively low temperatures. The reaction is completed within two hours at 100°.

The rearrangement occurs in the absence of solvents and without the appearance of a liquid phase when solid crystals of acetylchloro-aminobenzene are exposed to the radiation of a mercury-vapor lamp.

Mechanisms involving intermediate products cannot apply to the solid phase reaction.

THE CRYSTAL STRUCTURES OF AMMONIUM, POTASSIUM AND RUBIDIUM CUPRIC CHLORIDE DIHYDRATES

BY STERLING B. HENDRICKS AND ROSCOE G. DICKINSON

RECEIVED APRIL 25, 1927

PUBLISHED SEPTEMBER 2, 1927

Introduction

The low crystallographic symmetry of most salt hydrates and ammoniates has prevented the study of such compounds by x-ray methods. In an effort to comprehend more fully the geometrical relationship of water to the other components of such compounds we have studied the alkali cupric chloride dihydrates, $R_2CuCl_4 \cdot 2H_2O$ (where R represents ammonium, potassium or rubidium). These compounds form an apparently isomorphous series crystallizing in the ditetragonal bipyramidal class of the tetragonal system.¹ The axial ratios and observed densities of these compounds are given in Table I.

Large crystals, showing development of (111) and (100), were grown from aqueous solutions containing cupric chloride and the alkali chloride in the correct stoichiometrical quantities. Great caution was used in selecting crystals for the x-ray photographs, since twinning on (111)

¹ Groth, "Chemische Krystallographie" Engelmann, Leipzig, 1906, vol. I, pp. 355-356.

TABLE I

AXIAL RATIOS AND DENSITIES OF THE ALKALI CUPRIC CHLORIDE DIHYDRATES

Compound	Axial ratio $a:c$		Density	
	Goniometric	X-ray	Obs.	Calcd.
$K_2CuCl_4 \cdot 2H_2O$	1:0.7525	1:0.7405	2.410	2.41
$(NH_4)_2CuCl_4 \cdot 2H_2O$	1:0.7417	1:0.7415	2.01 (1.963)	1.98
$Rb_2CuCl_4 \cdot 2H_2O$	1:0.7441	1:0.7250	2.895	2.80

was common. The investigation was carried out by the use chiefly of Laue and spectral photographs interpreted with the aid of the theory of space groups.²

The Structure of Potassium Cupric Chloride Dihydrate

The Unit of Structure.—Spectral data for $K_2CuCl_4 \cdot 2H_2O$ are listed in Table II, and for the ammonium and rubidium salts in Tables III and IV, respectively. Col. 1 gives the crystallographic indices of the face under consideration; those without subscript refer to the original crystallographic axes, while indices with the subscript s. g. refer to the axes of the unit of structure. The angles of reflection, θ , of molybdenum K lines are given in Col. 4. For potassium cupric chloride dihydrate the smallest unit compatible with these spectral data has its a axis rotated 45° from the original crystallographic axis, and has $d_{100} = d_{010} = 7.45 \text{ \AA.}$ and $d_{001} = 7.88 \text{ \AA.}$ It contains $2.00 K_2CuCl_4 \cdot 2H_2O$. The method described by Kirkpatrick and Dickinson³ was used in making this restriction. No Laue data were found requiring a larger unit.

The Lattice and Space Group.—The observation that a Laue photograph made with the x-ray beam normal to (001) shows a fourfold axis

and four planes of symmetry requires the structure to be isomorphous with point group V_d , C_{4v} , D_4 or D_{4h} . The presence of reflections in the first order from planes with $h + k + l$ both odd and even as well as with $h + k$ both odd and even requires the lattice to be the simple tetragonal one Γ_1 . The following space groups based on this lattice and isomorphous with one of the above point groups are eliminated for the reasons given.⁴

D_{4h}^8 , D_{4h}^{11} , D_{4h}^{13} , D_{4h}^{16} , C_{4v}^8 , D_4^3 , D_4^4 , D_4^7 and D_4^8 , since these space groups do not have positions for two copper atoms.

D_{4h}^3 , D_{4h}^4 , D_{4h}^7 , D_{4h}^8 , D_{4h}^{11} , D_{4h}^{12} , D_{4h}^{15} and D_{4h}^{16} , since these require the absence in odd orders of $(h\bar{k}0)$ with $(h+k)$ odd; yet $(\bar{4}10)$, $(\bar{2}30)$, (650) were observed to be present in the first order.

D_{4h}^5 , D_{4h}^6 , D_{4h}^{11} , D_{4h}^{13} , C_{4v}^2 , C_{4v}^3 require the absence in odd orders of $(0kl)$ if k is odd; $(0\bar{7}1)$, (051) , $(05\bar{9})$ and $(01\bar{7})$ were observed in the first order.

D_{4h}^2 , D_{4h}^8 , D_{4h}^{10} , D_{4h}^{16} , C_{4v}^4 , C_{4v}^5 require the absence in odd orders of $(0kl)$ if l is odd; $(0\bar{7}1)$, (051) , $(05\bar{9})$, $(01\bar{7})$ were observed in the first order.

⁴ Astbury and Yardley, *Phil. Trans.*, **224A**, 221 (1924).

D_{4h}^2 , D_{4h}^4 , D_{4h}^6 , D_{4h}^8 , D_{4h}^9 , D_{4h}^{11} , D_{4h}^{13} , D_{4h}^{15} , C_{4v}^5 , C_{4v}^6 , C_{4v}^7 , C_{4v}^8 , V_d^2 and V_d^4 require the absence of odd order reflection form (hkl) with l odd; (331) and (551) were observed in the first order.

D_4^3 , D_4^4 , D_4^7 and D_4^8 require the absence of (001) in even orders not multiples of four; the second and sixth orders were observed.

Space groups not eliminated by the above considerations require the following general absences of reflection in odd orders: D_{4h}^{14} , D_{4h}^{14} , C_{4v}^{14} , V_d^1 none; D_{4h}^{14} , C_{4v}^{14} , $(0kl)$ with $(k+l)$ odd; V_d^3 , D_4^2 , D_4^5 , (100), D_4^5 , (001). The types of absences of first-order reflections required by D_{4h}^5 , V_d^3 , D_4^2 and D_4^5 are special cases of those required to be absent by D_{4h}^{14} and C_{4v}^{14} , that is, reflection in the *odd* orders from planes of the type $(0kl)$ with $(k+l)$ odd. No such planes were found to reflect. Reflections in odd orders were found to be absent from the following planes: (160), (001), ($\bar{8}01$), ($\bar{1}08$), (061), (702), (401), ($10\bar{4}$), ($30\bar{8}$), ($20\bar{7}$), ($40\bar{9}$), ($02\bar{9}$). Examination of the coördinate positions in space groups D_{4h}^{14} , D_4^1 , C_{4v}^{14} , V_d^1 , V_d^3 , D_4^2 , D_4^5 and D_4^5 showed that this criterion could be satisfied in a few special cases, but that the absence of reflection would be dependent on a relationship involving relative reflecting powers and parameters defining atomic positions. While such a relationship might be satisfied for one member of the isomorphous series, it probably would not give a satisfactory answer for another member, the postulate being made that great changes in structure do not take place between different members of this isomorphous series. Accordingly D_{4h}^{14} and C_{4v}^{14} , which have the same general criteria, alone remain. On account of the difficulty of treating C_{4v}^{14} further, the remainder of the investigation has been confined to the more symmetrical space group D_{4h}^{14} . The justification for this is that D_{4h}^{14} is in accord with such crystallographic evidence as we possess and leads to a structure in agreement with our x-ray data.

The Atomic Arrangement.—The following are all the special arrangements⁵ occurring in D_{4h}^{14} ; the general arrangement possesses 16 equivalent positions and does not concern us here.

D_{4h}^{14}	Two equiv. positions	(a) 000; $\frac{1}{2}\frac{1}{2}\frac{1}{2}$	(b) $00\frac{1}{2}$; $\frac{1}{2}\frac{1}{2}0$
	Four equiv. positions	(c) $0\frac{1}{2}0$; $0\frac{1}{2}\frac{1}{2}$; $\frac{1}{2}0\frac{1}{2}$; $\frac{1}{2}00$	
		(d) $0\frac{1}{2}\frac{1}{2}$; $0\frac{1}{2}\frac{1}{2}$; $\frac{1}{2}0\frac{1}{2}$; $\frac{1}{2}0\frac{1}{2}$	
		(e) $00w$; $00\bar{w}$; $\frac{1}{2}\frac{1}{2}w + \frac{1}{2}$; $\frac{1}{2}\frac{1}{2}\bar{w} - \frac{1}{2}$	
		(f) $uu0$; $\bar{u}\bar{u}0$; $\frac{1}{2} - u, u + \frac{1}{2}, \frac{1}{2}$; $u + \frac{1}{2}, \frac{1}{2} - u, \frac{1}{2}$	
		(g) $vv\frac{1}{2}$; $\bar{v}\bar{v}\frac{1}{2}$; $\frac{1}{2} - v, v + \frac{1}{2}, 0$; $v + \frac{1}{2}, \frac{1}{2} - v, 0$	
	Eight equiv. positions	(h) $0\frac{1}{2}u$; $\frac{1}{2}0u$; $\frac{1}{2}, 0, u + \frac{1}{2}$; $0, \frac{1}{2}, u + \frac{1}{2}$; $0\frac{1}{2}\bar{u}$; $\frac{1}{2}0\bar{u}$; $\frac{1}{2}, 0, \bar{u} - u$; $0, \frac{1}{2}, \bar{u} - u$	
		(i) $uv0$; $\bar{v}u0$; $v + \frac{1}{2}, \frac{1}{2} - u, \frac{1}{2}$; $u + \frac{1}{2}, \frac{1}{2} - v, \frac{1}{2}$; $\bar{u}\bar{v}0$; $\bar{v}\bar{u}0$; $\frac{1}{2} - v, u + \frac{1}{2}, \frac{1}{2}$; $\frac{1}{2} - u, v + \frac{1}{2}, \frac{1}{2}$	
		(j) uuv ; $uu\bar{v}$; $u + \frac{1}{2}, \frac{1}{2} - u, \frac{1}{2} - v$; $u + \frac{1}{2}, \frac{1}{2} - u, v + \frac{1}{2}$; $\bar{u}\bar{u}\bar{v}$; $\bar{u}\bar{u}v$; $\frac{1}{2} - u, u + \frac{1}{2}, v + \frac{1}{2}$; $\frac{1}{2} - u, u + \frac{1}{2}, \bar{v} - v$	

⁵ Wyckoff, *Carnegie Inst. Pub.*, 318, p. 97 (1922).

The completion of the structure determination requires the allocation of 2 Cu, 4 alkali, 8 Cl and 4 H₂O among the above coördinates, and the determination of the parameters involved. The large number of possible combinations of these coördinates makes this task at first sight hopeless. Fortunately, however, we have found a general characteristic of the reflections from one class of planes, which greatly simplifies the problem. This observation is that first-order reflections from planes with $h + k + l$ odd and l odd (designated Class 1a) are always of comparatively very small intensity while those from planes having $h + k + l$ odd and l even (designated Class 1b) are not, and this observation holds good not only for the potassium salt but also for the ammonium and rubidium salts.

TABLE VI

PARAMETER VALUES FOR WHICH D_{hk}^{14} STRUCTURE FACTORS, S, VANISH WHEN $h = k = l$ IS ODD

Arrangement	No. of equiv. pos.	h odd, k even, l even	Parameter values	
			h odd, k odd, l odd	h even, k even, l odd
(a)	2	S always zero	S always zero	S always zero
(b)	2	S always zero	S always zero	S always zero
(c)	4	S always zero	S always zero	S always zero
(d)	4	S always zero	S always zero	S always zero
(e)	4	S always zero	S always zero	S always zero
(f)	4	$u = \frac{1}{2}$	No solution	$u = \frac{1}{2}$
(g)	4	$u = \frac{1}{2}$	No solution	$u = \frac{1}{2}$
(h)	8	S always zero	S always zero	S always zero
(i)	8	$u = 0$ or $\frac{1}{2}$;	$u = 0$ or $\frac{1}{2}$;	$u = 0, \frac{1}{2}, \frac{3}{2}$ or $\frac{5}{2}$;
		v unrestricted	v unrestricted	v unrestricted
		or $v = 0$ or $\frac{1}{2}$;	or $v = 0$ or $\frac{1}{2}$;	or $v = 0, \frac{1}{2}, \frac{3}{2}$
		u unrestricted	u unrestricted	or $\frac{5}{2}$;
(j)	8			u unrestricted
		$u = \frac{1}{2}$;	$v = \frac{1}{2}$;	$u = \frac{1}{2}$;
		v unrestricted	u unrestricted	v unrestricted
				or $v = \frac{1}{2}$;
				u unrestricted

We have given in Table VI all of the values of the parameters (exclusive of those which lead to identical arrangements or coincidence of two atoms) for which that part of the structure factor due to each of the above arrangements becomes zero whatever may be the values of h , k and l , subject to the restrictions given at the head of each column. We may, without loss of generality, place the two copper atoms at (a); the copper atoms then contribute nothing to first orders from planes with $h + k + l$ odd. The presence of such reflections shows that some of the positions (f), (g), (i) and (j) must be occupied by alkali, chlorine or water, or some combination of them. This occupancy cannot be by one kind of atom alone in any *single* arrangement except (j), for only here can a parameter value (namely, v near $\frac{1}{2}$) be found which will make reflections of Class

1a weak without making those of Class 1b weak also. No other arrangement gives a solution common to Cols. 4 and 5 but not Col. 3 of Table VI. Only the 8 chlorine atoms can occupy (j). On the other hand, if more than one of the positions (f), (g), (i) and (j) are occupied, one of these positions cannot be occupied by an alkali atom, for then weakness of reflection in Class 1a would have to be ascribed to a suitable interference between alkali and chlorine or oxygen (or both). Such destructive interference in the case of the ammonium salt could hardly remain on substitution of potassium or the much heavier rubidium. The possibility that such interference occurs between chlorine and water likewise seems remote. There remains only the possibility that the chlorine atoms are non-equivalent, four being at (f) and four at (g). With this arrangement Class 1a and not Class 1b can become weak and, in general, only when u is nearly equal to v . We conclude, therefore: (1) that the alkali atoms are at (c), (d) or (e); (2) that the chlorine atoms are either all equivalent at (j) with v near $\frac{1}{4}$, or that they are two groups of four at (f) and (g) with u nearly equal to v .

The spectral data (Tables II, III, IV) show that with all three salts the second order from (001) was much weaker than the fourth, and that the second was relatively weakest from the rubidium salt, being of almost vanishing intensity in this case. The alternative chlorine positions which remain place the chlorine atoms either [(f) and (g)] equally in basal planes with the copper atoms, or (j) in basal planes practically half way between them. Simple calculations of the basal plane structure factors for the second and fourth orders make it evident that with the chlorine at (j) the alkali atoms must be at (c) in order to make the second order of the rubidium salt reasonably weak; and that with the chlorine at (f) and (g) the alkali atoms must be at (d), or at (e) with w near $\frac{1}{4}$. These conclusions require only the approximate use of atomic numbers or electron numbers and are not markedly dependent upon the position of the water molecule. The positions (e) for the alkali atoms involves placing three positive atoms in a line in a distance of 8 Å. and placing an alkali at about 2 Å. from a copper atom; this is regarded as so improbable that it has not been treated further. We are thus left with two main alternatives: (1), 2Cu at (a), 8Cl at (j) with v near $\frac{1}{4}$, 4 alkali at (c), 4H₂O at (d), (e), (f) or (g); (2), 2Cu at (a), 4Cl at (f) and 4Cl at (g) with u nearly equal to v , 4 alkali at (d), 4H₂O at (c), (e), (f) or (g).

A piece of evidence against Arrangement (j) for a chlorine atom is the strength of the fourth order from (101) as compared with the second; in the case of the ammonium compound the fourth was practically as strong as the second, thus requiring a larger structure factor for the fourth order. Neglecting water, the structure factors given by the arrangement involving (j) are

$$n = 2 \quad S = 2\overline{Cu} + 4\overline{alk} + 8\overline{Cl} \cos 4\pi u \cos 4\pi v$$

$$n = 4 \quad S = 2\overline{Cu} + 4\overline{alk} + 8\overline{Cl} \cos 8\pi u \cos 8\pi v$$

For the values $u = \frac{1}{4}$, $v = \frac{1}{4}$, these both reduce to $2\overline{Cu} + 4\overline{alk} + 8\overline{Cl}$. The effect of changing the parameter values away from $\frac{1}{4}$ is to reduce the $8\overline{Cl}$ term for all values of u or v near $\frac{1}{4}$, and to reduce it more in the fourth than in the second order (the only values of u and v compatible with other data are sufficiently near to $\frac{1}{4}$ for this to apply). Hence, the only way in which the fourth can be made greater than the second is by water; it is regarded as doubtful whether the scattering power of water is great enough to account for the observed difference. On the other hand, the arrangement with (Cl) at (f) and (g) leads with parameter values determined below to a much larger structure factor for the fourth than for the second order even when water is omitted.

A similar piece of simple evidence comes from powder photographs of the potassium and of the ammonium salt made with molybdenum $K\alpha$ radiation in a General Electric Company cassette. The strong line due to (110) second order was stronger than that due to (101) second order occurring at a slightly smaller angle. As the number of cooperating planes for (110) is only half that for (101), the structure factor must be the greater for (110). Arguments similar to those used above again favor chlorine at (f) and (g) rather than at (j).

Other data which again eliminate (j) are the Laue photographic comparisons: (551) > (351); (151) > (241); (632) > (542). These have the disadvantage of involving only small intensity differences, but the advantage of not involving relative reflecting powers.

Finally, the alternative involving (f) and (g) as chlorine positions remains to be considered. In this case the possibility of water also being at (f) and (g) is removed by the chemical improbability of such a structure, by the necessary close approach of the chlorine and copper atoms and the water molecule, and also by the fact that planes having $h + k + l$ odd and l odd are uniformly weak no matter what the interplanar distance is.

Evaluation of the Parameters.—In order that the spectral data from (101)_s shall be satisfied, u and v must be in the region 0.18 to 0.32. The following comparisons from Photograph 2 restrict the parameters to the region (0.21, to 0.23); (418) > (652), (652) > (643), (652) > (128). This region could not be further restricted by intercomparisons not involving assumptions concerning relative reflecting powers. The near equalities of the intensities of reflections (386) \geq (4.1.10) and (652) > (128), together with the required separation of the two parameters, suggest $u = 0.213$ and $v = 0.217$, or vice versa, as the most probable values.⁶ A consideration of other data is necessary to distinguish between u and v .

⁶ The values $u = \frac{1}{4} - \beta$ and $v = \frac{1}{4} - \alpha$ lead to the same structures as the values $u = \alpha$ and $v = \beta$ and hence do not require separate consideration.

The following observed inequalities of reflections, $(473) > (471)$, $(653) > (651)$, $(387) > (385)$, between planes having $h + k + l$ even and l odd, require oxygen to be at (e), with a value of w between 0.250 to 0.333; these comparisons do not involve the assumption of numerical relative reflecting powers. A closer restriction of w can be made by comparisons affected by the value of the chlorine parameter; $(149) > (167)$, $(219) > (651)$ require w to be between 0.315 and 0.333. We have taken 0.32 as an approximate value.

TABLE VII

* Cl is to be taken as unity.

The only remaining undetermined factor is whether $u = 0.213$, $v = 0.217$, or the reverse. This question can be answered only by a consideration of data from all types of planes—it will depend upon relative reflecting powers as well as the usual assumptions of the methods of analysis of Laue photographs. The final tabulation of Laue data as given in Table VII, compiled from Photograph 2, shows the agreement obtained with $u = 0.213$ and $v = 0.217$. The structure factors have been calculated, first using atomic numbers and then using a reflecting power of copper increased by 50%. No data either from Laue photographs or spectral photographs were obtained in disagreement with these parameter values.

The Crystal Structure of Ammonium and Rubidium Cupric Chloride Dihydrates

The analysis of the data obtained from Laue and spectral photographs of these two compounds leads to conclusions similar to those given above. The values of the parameters were determined under the assumption that u_{Cl} and v_{Cl} did not differ by more than 0.015 (the value found in the case of potassium cupric chloride dihydrate being 0.004). The agreement between the observed intensities and calculated structure factors for spectral data is evident by reference to Tables III and IV. Table VIII gives a summary of the results obtained from the three compounds.

TABLE VIII

A SUMMARY OF PARAMETER VALUES, UNIT DISTANCES AND ATOMIC DISTANCES IN THE COMPOUNDS $R_2CuCl_4 \cdot 2H_2O$ ($R = NH_4, K$ or Rb)

Compound	$d_{100} = d_{010}, \text{\AA.}$	$d_{001}, \text{\AA.}$	u_{Cl}	v_{Cl}	w_0
$(NH_4)_2CuCl_4 \cdot 2H_2O$	7.58	7.96	0.217	0.221	0.320
$K_2CuCl_4 \cdot 2H_2O$	7.45	7.88	.213	.217	.318
$Rb_2CuCl_4 \cdot 2H_2O$	7.81	8.00	.213	.217	.330

Compound	Atomic distances, \AA.				
	Cu to nearest oxygen	Cu to nearest Cl at (f)	Cu to nearest Cl at (g)	Cu to nearest R	R to nearest Cl at (f)
$(NH_4)_2CuCl_4 \cdot 2H_2O$	2.55	2.44	3.14	4.28	3.28
$K_2CuCl_4 \cdot 2H_2O$	2.51	2.37	3.15	4.21	3.32
$Rb_2CuCl_4 \cdot 2H_2O$	2.64	2.41	3.20	4.38	3.43

Discussion of the Structure

Geometrical and Chemical Significance of the Structure.—The unit of structure containing two $R_2CuCl_4 \cdot 2H_2O$ is shown in Fig. 1. In this structure each copper atom is immediately surrounded by two oxygen atoms and four chlorine atoms, two of the chlorine atoms being at a distance different from the other two. The average copper to chlorine distance is 0.75 \AA. greater in one case than in the other (see Table VIII).

Each alkali atom is surrounded by four oxygen atoms, four copper atoms

and eight chlorine atoms. In this case, although the eight surrounding chlorine atoms are not all equivalent, they are practically equidistant from the alkali atom. The small difference in distance is necessary so that the Laue data can be satisfied (see next section). The average alkali to chlorine distance in these compounds is *ca.* 0.14 Å. greater than that of the corresponding alkali halides having the sodium chloride type of structure.

In the case of potassium chlorostannate K_3SnCl_6 ⁷ and of $NiCl_2 \cdot 6NH_3$,⁸ a group of six chlorines or ammonias is equidistantly placed around the central metal atom, the geometrical association being quite definite. Similarly in the case of the alkali cupric chloride dihydrates, each chlorine or water has one copper atom which is nearer to it than any other copper atoms are; and if the chlorine or water be regarded as associated with this copper atom, and the process repeated for all chlorine and water, the result is an array of cupric chloride dihydrate groups.

These groups are all alike and are octahedral in shape, but not regular. However, any physical unity or stability cannot be attributed to these groups on such purely geometrical grounds. Indeed, in view of the considerable inequality in the two copper to chlorine distances, it is natural to assume that the forces exerted by the copper on

Fig. 1.—The unit of structure of the alkali cupric chloride dihydrates. ▽, Cl at (*f*); △, Cl at (*g*); ○, Cu; ●, NH_4 , K or Rb; ○, O.

the surrounding chlorine atoms are quite unequal. This inequality may well correspond to a lack of stability of the coördination group, which would be in agreement with the behavior of the substance in solution as a double salt rather than as a complex salt.

These compounds represent a new structural type. Although they have the same space-group symmetry as magnesium fluoride, they are not related to magnesium fluoride in the simple manner in which potassium chlorostannate is related to calcium fluoride.

Discussion of the Method of Analysis

In making use of absences of reflections from planes in positions to reflect, in order to determine the correct space group, it is desirable to examine combinations of special positions in the eliminated space groups

⁷ Dickinson, *THIS JOURNAL*, **44**, 276 (1922).

⁸ Wyckoff, *ibid.*, **44**, 1239 (1922).

in order to be certain that the observations could not be accounted for by giving particular values to the parameters. In the present case such a method reduces the number of space groups to two, C_{4v}^4 and D_{4h}^{14} . Since C_{4v}^4 can approximate arrangements from D_{4h}^{14} as closely as desired, we have made the *assumption* that the crystallographically assigned symmetry is correct. Such an assumption has proved to be incorrect in some cases (penta-erythritol, sodium periodate, etc.).

An observation of great value to us in the structure determination was the presence of weak reflections from planes with $h + k + l$ odd and l odd. It is conceivable that these reflections appear only because of a dissymmetry in a particular kind of atom, chlorine for instance. However, when two such planes reflected at the same wave length, and the one with the smaller interplanar distance was the more intense, its structure factor, with a separation of the value of u and v not exceeding (0.03) in case of chlorine (f) and (g), was always found to be the greater of the two. This is of further interest since arrangements with chlorine at (j) could not account for such an observation.

The elimination of the arrangement with chlorine at (j) is not as straightforward as one might wish. It is based upon rather close Laue comparisons, and a general disagreement with the spectral data. Reflections for which chlorine at (j) and at (f) and (g) would lead to considerably different intensities require some knowledge of reflecting powers in their treatment.

The determination of the chlorine parameters has been made independently of relative reflecting powers; but our determination of which value represents u and which v is not a very good one. The difference between the two is, however, very small.

It is not probable that oxygen reflects strongly enough to be a factor governing markedly the intensity of the Laue spots. Small intensity differences in our data require a parameter for oxygen, however. The parameter determination in the case of oxygen at (e) is of approximate character only. The data, without assumptions concerning relative reflecting powers, could not be explained by placing oxygen at (c) or (d). This elimination of (c) and (d) is based on several comparisons, all of which are necessarily close.

This investigation was aided financially from a grant made to Professor A. A. Noyes by the Carnegie Institute of Washington.

Summary

The structures of crystals of ammonium, potassium and rubidium cupric chloride dihydrates have been investigated by means of Laue and spectral photographs interpreted with the aid of the theory of space groups. The unit of structure, based on a simple tetragonal lattice,

contains two $R_2CuCl_4 \cdot 2H_2O$. The space-group symmetry is probably D_{4h}^{14} with 2Cu at (a), 4 alkali at (d), 4Cl at (f), 4Cl at (g) and $4H_2O$ at (e). The compounds seem to have "double salt" characteristics.

THE CONDUCTIVITY OF ACIDS AND SALTS IN LIQUID AMMONIA¹

BY FRANCIS A. SMITH

RECEIVED MAY 21, 1927

PUBLISHED SEPTEMBER 2, 1927

In the course of the development of the system of compounds derived from liquid ammonia as a solvent, by Franklin² and his associates, it was desired to know the extent to which certain acids and salts would ionize when dissolved in liquid ammonia. This information was designed to indicate whether or not metallic salts of acids derived from the ammonia system, when dissolved in liquid ammonia, would ionize to a greater extent than their respective acids. This conspicuous property of salts of aquo-acids in water solution would thus serve to test the validity of the classification of the former as true salts.

Also it was hoped that such information would be a useful addition to existing knowledge of the properties of substances dissolved in liquid ammonia.

Some of the data obtained by Franklin³ and by Franklin and Kraus⁴ are made use of for purposes of comparison.

Treatment and Expression of Results

The following notation has been used to express the designated quantities: R , measured resistance; C , cell constant; v , dilution, in liters per mole; Λ , molecular conductivity; Λ_∞ , the value approached by Λ as the dilution increases; K , the ionization or equilibrium constant.

The conductivity curves of the substances measured, with some of the curves of Franklin and of Franklin and Kraus, have been plotted together in Fig. 1 for comparison.

The graphical methods of Kraus and Bray⁵ have been used, where applicable, to evaluate Λ_∞ and K , and these values are given in Tables I and II.

¹ From a thesis presented to the Department of Chemistry and the Committee on Graduate Study of Stanford University in 1925 in partial fulfillment of the requirements for the degree of Doctor of Philosophy. The work herein described was done under the direction of Dr. E. C. Franklin.

⁵ Kraus and Bray, *THIS JOURNAL*, **35**, 1315 (1913).

Experimental

The measurements were made at -33.5° , using cells described by Elsey,⁶ and technique which differs only in certain details from that described by him, or by Franklin and Kraus.^{4a}

The cell constants were redetermined, using 0.02 *M* potassium chloride at 20 and at 0° , and 0.01 *M* potassium chloride at 18° , prepared by the method of Kraus and Parker,⁷ and using the values for the specific conductivity given by Kohlrausch and Holborn,⁸ and by Kraus and Parker, respectively.

The resistance measurements were made by comparison with a standard 1-100,000 ohm box of Curtis coils, by means of a Kohlrausch drum slide wire, both made by Leeds and Northrup, and used by Elsey.

The alternating current was obtained from a micro-hummer giving a sine wave current with a frequency of 1000.

The telephone current was amplified by means of a device described by Hall and Adams.⁹

The entire apparatus was shielded with grounded metal. The wires leading from the cell vessel were No. 18 double cotton covered copper, enclosed in separate grounded lead tubes. These wires under operating conditions had a resistance of 0.16 ohm, which was deducted from all resistance measurements.

Satisfactorily sharp minima were obtained by the use of capacity in parallel with the resistance box.

For reasons set forth in the following paper, the resistance measurements herein described were made by means of the concentric pair of electrodes only.

A measured volume of a solution of determined concentration and resistance was diluted with successive measured portions of pure solvent, distilled from the reservoir and condensed directly in the conductivity cell. The new concentration was calculated, and the new resistance measured, after each dilution.

All results have been corrected by subtracting the specific conductivity of the solvent, as obtained before and after each series of measurements, from that of the solution.

The specific conductivity of the solvent was usually from 0.1 to 0.2×10^{-6} mhos.

Preparation of Materials

The substances used in making these measurements have been obtained from several sources. Two were Kahlbaum preparations, ten were

prepared or purified by the writer, and ten were prepared and purified by other workers, notably W. L. Burdick, J. S. Blair and F. W. Bergstrom, to whom thanks are due. In cases of uncertainty the purity has been verified by analysis and, with the exception of dicyanodiamide and melamine, the purity of all are within the limits of the experimental error of the measurements.

Results

The molecular conductivity at $\log v = 3.0$ of seven acids and their respective alkali-metal salts is shown in Table I.

TABLE I
THE CONDUCTIVITY OF ACID AND SALT COMPARED

Electrolyte	Formula	$\Delta_{\log v = 3.0}$	$10^4 K$	
I. Potassium <i>m</i> -nitrobenzene-sulfonamide	$\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{SO}_2\text{NHK}$	201	275	15.0

20. Trisodium tricyanomelamine	$[\text{NaN}(\text{CN})_2]_3$	100
21. Tripotassium hydromelionate	$\text{K}_3\text{C}_9\text{N}_{13}$	244

Values of Λ at this same dilution for other acids and salts are given in Table II.

The dilution $\log v = 3.0$ was chosen because the values of Λ are perhaps better distributed in this region than in any other which includes as many curves.

Values of Λ_∞ and K could not be determined by the graphical method of Kraus and Bray with substances not binary electrolytes; and the use of this method with binary electrolytes of very low conductivity leads to unreasonably low values for Λ_∞ , with correspondingly high values for the degree of dissociation and for K . Therefore, no attempt has been made to assign values to those substances.

The number assigned to a substance in the tables is the same as that which designates the curve for that substance in Fig. 1. The Roman numerals refer to substances measured by Franklin and Kraus.

X—Franklin and Kraus: I, Potassium *m*-nitrobenzenesulfonamide; II, *m*-Nitrobenzenesulfonamide; III, Mercury succinimide; IV, Cyanamide. Fig. 1.—The conductivity of acids and salts in liquid ammonia.

Discussion

On account of several considerations treated in the following paper, and because with many of the substances it is difficult to attain and main-

tain any considerable degree of purity, no great accuracy can be claimed for the results presented above. However, the least accurate of them is probably not in error by more than 5%.

It is immediately evident from Fig. 1 that only a few of the curves correspond more than approximately to the dilution law of Kraus and Bray.⁵ Obviously many of the substances do not behave as simple binary electrolytes.

A point of inflection at about $\log v = 4.5$ seems to be common to most of the curves in Fig. 1, at which point the slope again increases.

The curves as a group approach a value just under 300 for Λ_{∞} . The fact that in certain cases curves of nearly ideal form were obtained, serves as a check upon the manipulation as well as upon the accuracy with which the dilutions could be made.

The curves of the acid amides, the polymers of cyanamide and α -triphenylguanidine have not been plotted in Fig. 1 because of the extremely small values of Λ involved.

One might expect the acid amides to be poor conductors, since they are analogs of the weak carboxylic acids. Although they are formally dibasic acids, only one hydrogen atom can be replaced by potassium in liquid ammonia solution, and it is probable that the ionization of the second is immeasurably small. This is in harmony with the fact that their salts behave essentially as binary electrolytes.

As may be seen from Table I, the salt is in every case but one a better conductor than the corresponding acid. The difference, however, is small in case the acid is one of the so-called "strong" acids. Possibly since the "strong" acid is capable of forming a stable ammonium salt, it does so, and the conductivity measured is that of the ammonium salt. Succinimide, for example, is stable and has weak acid properties in water solution.

The mercury salt of succinimide (Fig. 1) runs true to the form of mercury salts in general, exhibiting a very low conductivity, as compared with most salts, in liquid ammonia, as in water.

In considering the ammonio-carbonic acids,¹⁰ it is interesting to note that the conductivity of both acids and salts, in so far as it has been measured, increases with de-ammonation of the acids, and decreases with polymerization. The most completely ammonated acid, and the more polymerized acids, are very poor conductors, while the monomolecular de-ammonation product, $\text{HN}(\text{CN})_2$, is a strong acid even in water solution. This is in harmony with results reported by Madelung and Kern,¹¹ who show that dicyanimide, $\text{HN}(\text{CN})_2$, is a strong acid in water solution, and that the triamer, tricyanomelamine, is a somewhat weaker

¹⁰ Franklin, *THIS JOURNAL*, **44**, 486 (1922).

¹¹ Madelung and Kern, *Ann.*, **427**, 1 (1922).

one in practically the same ratio that has been found by the writer for the conductivity of their respective salts in liquid ammonia solution.

Sulfur nitride is noteworthy for the reason that it is a good conductor, and that the form of the curve is that of a binary electrolyte. Sulfur nitride has been shown¹² to be a mixed anammonide of ammonio-sulfurous, and ammonio-thiosulfuric acids. The possibility of ammonation, with the resulting formation of the above acids, is precluded by the small slope of the curve, and the absence of insoluble material. It is suggested that the substance dissociates into the two anammonous radicals which on ammonation would give the respective acids.

In conclusion, the writer wishes to express the most sincere thanks to Dr. E. C. Franklin for assistance, suggestions and advice which always have been readily available.

Summary

Conductivity measurements have been made in liquid ammonia solution at -33.5° on twenty-two substances.

In every case but one, the alkali metal salt of an acid proved to be a much better conductor than the acid itself.

The acid amides are very poor conductors, while their alkali metal salts are good conductors and behave as binary electrolytes.

The conductivity of the ammonio-carbonic acids, and their alkali metal salts, increases with de-ammonation of the acid, and decreases with polymerization.

The graphical method of Kraus and Bray has been used to evaluate Λ_{∞} and K , for twelve substances.

A SOURCE OF ERROR IN CONDUCTIVITY MEASUREMENTS¹

By FRANCIS A. SMITH

RECEIVED MAY 21, 1927

PUBLISHED SEPTEMBER 2, 1927

In studying the literature on the measurement of electrolytic conductivity, one meets with statements of conclusions such as those of Washburn,² and of Schlesinger and Read.³

The former states, in substance, that a cell should be designed, in resistance capacity, for the particular solution the resistance of which is to be measured in it; and that only solutions having resistances varying

¹² Unpublished observations made in this Laboratory.

¹ See preceding paper. Since this paper was first prepared, a paper by Randall and Scott, *THIS JOURNAL*, 49, 636 (1927), has appeared which presents similar results.

² Washburn, *THIS JOURNAL*, 38, 2431 (1916).

³ Schlesinger and Read, *ibid.*, 41, 1727 (1919).

within rather narrow limits are suited for use with a cell having that particular resistance capacity.

The latter show that the value of the cell constant depends upon the resistance of the solution by means of which it is determined, and should be known for all resistances within the range of the measurements for which the cell is to be used.

The use by the writer⁴ of a conductivity cell containing three electrodes provided a striking corroboration of the above conclusions, probably on account of the design of the cell and the method of making the measurements. The electrodes consisted of three co-axial cylinders open at the

Fig. 1.—Conductivity curves of NH_4NO_3 in liquid NH_3 , resulting from measurements of resistances of two cells formed by three electrodes in the same solution.

ends, two of which were concentric and close together, and the third, at some distance from the others, presented its edge to the edges of the others.

The measurements were made by diluting a measured volume of a solution of known concentration and resistance with successive measured portions of pure solvent, calculating the new concentration, and measuring the new resistance after each dilution.

Fig. 1 shows the ordinary conductivity curves of ammonium nitrate in liquid ammonia solution. The values of Λ for one of the curves were calculated from the measured resistances of the cell formed by the con-

⁴ See preceding paper.

centric pair of electrodes, and the values for the other curve, from the distant pair of electrodes, using the corresponding cell constants, determined as described in the preceding paper.

It is evident that as the resistance changes there is a change not only in the cell constants, but also in the ratio which they bear to one another, and that the values of Λ determined from the two cells are concordant only in that region of concentration and resistance in which the 0.02 *M* and 0.01 *M* potassium chloride solutions used to determine the cell constants also fall.

The intersection of the two curves (Fig. 1) occurs at a concentration near 0.02 *M*, and the resistances of the concentric and distant cells at the near-by plotted points were 17.73 ohms, and 3574 ohms, respectively.

The resistances of the same cells containing aqueous potassium chloride are set forth in Table I.

TABLE I

THE RESISTANCES AND RESISTANCE RATIOS OF THE CELLS CONTAINING THE AQUEOUS POTASSIUM CHLORIDE SOLUTIONS WITH WHICH THE CELL CONSTANTS WERE DETERMINED

KCl aq.	Concentric cell		Distant cell	
	<i>R</i> (ohms)	<i>R</i> _{0.01 M} / <i>R</i> _{0.02 M}	<i>R</i> (ohms)	<i>R</i> _{0.01 M} / <i>R</i> _{0.02 M}
0.01 <i>M</i>	43.80		8860	
		2.033		2.033
0.02 <i>M</i>	21.55		4357	

It is seen that the ratio of the resistances of these two solutions is the same for both cells. Thus the criterion of reliability imposed by Taylor and Acree⁵ is complied with by these cells, notwithstanding their demonstrated unreliability, when used with solutions the resistances of which vary greatly from those of the potassium chloride solutions referred to in Table I.

In Fig. 2, values of the ratio of the resistance measured by means of the distant pair of electrodes to that measured by means of the concentric pair, are plotted against values of the logarithm of the resistance of the distant pair. The data were obtained from solutions of ammonium nitrate, and ammonium chloride, in liquid ammonia, and of potassium chloride in water.

It is evident that the resistance measured between the distant pair of electrodes increases more and more rapidly than that measured between the concentric pair, until the limiting resistance of the former is reached.

It had previously been found that when the walls of the cell vessel were wet with either water or ammonia, the order of magnitude of the resistance measured between either pair of electrodes never exceeded 10⁶ ohms. Consequently, on diluting a solution, as the resistance meas-

⁵ Taylor and Acree, *THIS JOURNAL*, **38**, 2409 (1916).

ured between the distant pair of electrodes reaches this maximum value, any further dilution causes a sharp decrease in the ratio of the resistances of the two cells. This condition is evidenced in Fig. 2 by the break at *m*.

It might be expected that the ratio of the resistances of the two cells would be constant, if the various factors such as effective electrode area and effective distance between electrodes remain constant. Evidently this is not the case.

The conditions assumed by Washburn² as a basis for the design of conductivity cells are, among others, plane parallel electrodes having a relatively large surface area, and separated by a relatively small distance. These conditions obviously are not fulfilled in the case of the cell formed by the distant pair of electrodes arranged edge to edge.

Fig. 2.—The effect of dilution on the ratio of the resistances of two cells formed by three electrodes in the same solution.

Obviously, unless the cell constant has been evaluated by means of suitably prepared solutions of known specific conductivity, which have resistances up to the highest value to be measured with the cell, all measurements made over a considerable range of resistances with a single cell are in error because the cell constant changes with resistance.

Especially liable to such error are such measurements as have been made by Franklin and Kraus,⁶ and by Franklin,⁷ Elsey,⁸ the writer⁴ and others, over a wide range of resistances by the process of dilution.

In this type of work it was the usual procedure to change from the

⁶ Franklin and Kraus, *Am. Chem. J.*, 23, 277 (1900).

⁷ Franklin, *Z. physik. Chem.*, 69, 272 (1909).

⁸ Elsey, *THIS JOURNAL*, 42, 2454 (1920).

distant pair to the concentric pair of electrodes as soon as the resistance measured between the latter exceeded 100 ohms, in order to minimize the heating effect of the current at low resistances. So long as this procedure was followed, no discrepancy became apparent, since the change was made in the region in which the corresponding values of Λ were concordant.

Elsey⁹ states that in case the change was made to the concentric pair of electrodes when their resistance was below 100 ohms, the heating effect of the current was noticeable, and that below 75 ohms there was a marked discrepancy between the corresponding values of Λ obtained from the two pairs of electrodes.

This discrepancy is indicated in Fig. 1 by the divergence of the curves for ammonium nitrate below their point of intersection, and is bound up with a shift in the bridge setting due to polarization, treated by Washburn,⁹ rather than with the heating effect of the current, or a changing cell constant. A rising temperature would produce a change in the direction opposite to that of the error indicated. The effect of a changing cell constant in this region is undoubtedly negligibly small. The shift in the bridge setting resulting when capacity is used to sharpen the telephone minimum which had been rendered indeterminate by polarization in a concentrated solution, most marked in "set-up B,"¹⁰ was in the direction of increasing resistance or decreasing values of Λ , and is probably the source of the discrepancy noted by Elsey.

Summary

The writer offers data in support of conclusions of Washburn and of Schlesinger and Read, showing that the use of a conductivity cell should be restricted to solutions having resistances of the same order of magnitude as those of the solutions used to determine the cell constant, on account of the fact that the cell constant changes with the resistance of the solution measured.

The effect of doubling the resistance of the solution between the concentric pair of electrodes of a three electrode cell was to slightly more than double the resistance of the solution between one of the concentric pair and the distant electrode. This effect amounted to about 5% at a dilution of one thousand liters per mole, and increased with dilution up to the highest resistance that could be measured between the distant pair of electrodes.

A COMPUTATION OF THE FREE ENERGY AND FUGACITY IN GASEOUS MIXTURES OF ETHYLENE AND ARGON

BY G. E. GIBSON AND BENJAMIN SOSNICK

RECEIVED MAY 25, 1927

PUBLISHED SEPTEMBER 2, 1927

Introduction and Discussion of Results

The determination of the fugacity or free energy of a gas in a mixture is of considerable practical and theoretical interest. Lewis and Randall¹ consider it likely that almost any gaseous solution would be nearly perfect, that is, at a given temperature and total pressure the fugacity of any constituent would be proportional to its mole fraction or partial pressure.²

Fig. 1.—Deviation of argon in ethylene-argon mixtures from the rule of Lewis and Randall.

The partial pressure here is defined as the product of the mole fraction and the total pressure. The only data available in the literature for an accurate calculation of the fugacities in a gaseous mixture are those of Masson and Dolley,³ who determined the isotherms of gaseous mixtures of varying composition of argon and ethylene at pressures from 30 to 125 atmospheres

¹ Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923.

² In a recent article by Lurie and Gillespie [THIS JOURNAL, 49, 1154 (1927)] this rule is found to hold fairly well for the Haber equilibrium at pressures up to about 13 atm. The deviations from Dalton's law are too small, however, at these pressures for an adequate test of the rule.

³ Masson and Dolley, *Proc. Roy. Soc. (London)*, 103A, 524 (1923).

at 24.95° . The fugacities of both constituents have been calculated from these data and the results are shown graphically in Figs. 1 and 2. Details of the calculation will be given in the next section. In Fig. 1 (2) the ratios of $f/f^\circ N$ for argon (ethylene) are plotted as ordinates for various mole fractions, against the pressure in atmospheres as abscissas. Here f is the fugacity of the component under consideration, f° the fugacity of the pure component at the pressure of the mixture and N its mole fraction. The graphs show clearly the deviations of these mixtures from the perfect solution represented by the horizontal line $f/f^\circ N = 1$. In the limiting case, that of argon at zero concentration and about 100 atmospheres, the fugacity is nearly twice the value calculated on the assumption of a per-

Fig. 2.--Deviations of ethylene in ethylene-argon mixtures from the rule of Lewis and Randall.

fect solution. Thus the error made in calculating the partial molal free energy on the assumption of a perfect solution is given by the difference $RT \ln f - RT \ln f^\circ N$, which in this extreme case for argon is about 440 calories. Up to about 50 atmospheres the rule of Lewis and Randall is very closely obeyed, the maximum deviation for argon at zero concentration at this pressure being about 96 calories.

Theory of the Calculation of the Fugacities from the Isotherms of Binary Mixtures

Consider a system consisting of n_1 moles of component I and n_2 moles of component II. Let its volume at total pressure P and absolute temperature T be V . The partial molal volume, \bar{v}_1 , of constituent I is defined by the equation

$$\bar{v}_1 = \frac{\partial V}{\partial n_1} \quad (1)$$

and similarly for \bar{v}_2 . The change in free energy in removing one mole of constituent I from a mixture at pressure P to a mixture of the same concentration at pressure P' is given by

$$\Delta F = \int_P^{P'} V dP \quad (2)$$

The ratio of the fugacities is then given by the equation

$$\ln \frac{f'}{f} = \frac{\Delta F}{RT} = \frac{1}{RT} \int_P^{P'} \bar{v} dP \quad (3)$$

The arbitrary constant in the fugacity is determined by making the fugacity of a perfect gas equal to its pressure. From these equations it is possible to calculate the fugacity of the constituents, when the total volume is known as a function of pressure and composition. Equation 3 is, however, not of convenient form for actual computation, and for this purpose may be transformed as follows. Defining the quantity α by the equation

$$\alpha = \frac{RT}{P} - \bar{v} \quad (4)$$

and noting that at zero pressure $f = NP$, we obtain by substitution

$$RT \ln f = RT \ln NP - \int_0^P \alpha dP \quad (5)$$

or substituting base ten logarithms for natural logarithms, we obtain with $R = 82.07$ cc. atmos. per degree

$$\log f = \log NP - \frac{1}{189.0T} \int_0^P \alpha dP \quad (6)$$

In Equation 6, f and P are expressed in atmospheres and α in cubic centimeters. In order to obtain α we must first calculate \bar{v} , and here again the basic equation, Equation 1, is not in a convenient form for computation. We have, therefore, made use of the method described in the note of Sosnick.⁴ For partial molal volumes, Sosnick's equation becomes

$$\bar{v}_1 = v_1 + \Delta + N_2 \frac{d\Delta}{dN_1}, \quad (7)$$

where v_1 is the molal volume of pure constituent I and Δ is defined by the equation

$$\Delta = v - (N_1 v_1 + N_2 v_2) \quad (8)$$

where $v = V/(n_1 + n_2)$ is the molal volume of the mixture and v_1 and v_2 are the molal volumes of the pure constituents.

The calculation thus resolves itself into the computation of N_1 , N_2 , v_1 , v_2 and v from the data of Masson and Dolley,³ the graphical evaluation of \bar{v}_1 and \bar{v}_2 , using Equations 7 and 8, and the evaluation of the fugacity by graphical integration, using Equations 4 and 6.

⁴ Sosnick, Note, THIS JOURNAL, 49, 2255 (1927).

Calculation of the Fugacities in the Mixtures of Ethylene and Argon From the Data of Masson and Dolley

Masson and Dolley³ express their results in terms of "density D " which they define by

$$D = \frac{\text{sum of separate volumes at 1 atm.}}{\text{volume of mixture at } P \text{ atm.}} \quad (9)$$

The composition is expressed as percentage by volume of the separate constituents at one atmosphere. In order to calculate the mole fraction N from the volume per cent. V.P. we first obtain the molal volumes v_1 and v_2 of argon and ethylene, respectively, from the liter weight L of these gases, namely, $L_A = 1.781$ g. per liter at 0° and 1 atm.⁵ and $L_{C_2H_4} = 1.2609$ g. per liter at 0° and 1 atm.,⁶ and then employ the equations

$$N_1 = 1 - N_2 = (V.P.)_1/v_1 / \left(\frac{(V.P.)_1}{v_1} + \frac{100 - (V.P.)_1}{v_2} \right) \quad (10)$$

The molal volumes, v , of the mixture are now obtained from the equation

$$v = \frac{N_1 v_1 + N_2 v_2}{D} \quad (11)$$

and are given in Table I.

From Table II the values of $\alpha = RT/P - \bar{v}$ (Equation 4) were calculated and are plotted against P for various mole fractions in Fig. 3. The values of $\int_0^P \alpha dP$ were obtained by graphical integration of these curves, and thence by Equation 9 the values of $\log f$ from which the curves of f/f^N plotted in Figs. 1 and 2 were derived. The free energies given in Tables III and IV were obtained by multiplying the values of $\log f$ by $1364.9 = (2.3026RT)$.

In order to show the deviations of the two gases from the ordinary perfect gas laws for mixtures, the values of f/NP have been calculated and are shown in Fig. 4.

It is difficult to give an estimate of the accuracy of the calculated fugacities. The errors introduced in the course of the calculations are certainly much less than the probable experimental error. Making reasonable but very liberal assumptions as to the experimental uncertainty, based on the irregularities in the curves of Δ (Equation 8) against N , we estimate the limit of error in the fugacities to be as follows.

1. The greatest errors occur in the values for argon at zero concentration, that is, for argon in pure ethylene. They range from a few hundredths of a per cent. at one atmosphere to a maximum of 7% at 125 atmospheres. With increasing mole fractions of argon the uncertainty in the fugacities at each pressure diminishes until in pure argon the error limit varies from a few hundredths of one per cent. at one atmosphere to 1.5% at 125 atmospheres.

2. For ethylene at zero concentration the error ranges from a few

hundredths of a per cent. at one atmosphere to 4.6% at 125 atmospheres, diminishing slightly with increasing mole fraction at each pressure. In pure ethylene the error ranges from zero to 3.5%.

Fig. 4.—Graphical representation of the fugacities and deviations from the perfect gas law $f = NP$ of ethylene and argon in their mixtures.

Summary

In order to test the rule of Lewis and Randall, that the fugacity of a constituent in a mixture of gases is the product of the mole fraction and the fugacity of the pure constituent at the pressure of the mixture, the fugacities of ethylene and argon were calculated from the experimental data of Masson and Dolley. The rule was found to hold fairly well at low pressures. At about 50 atmospheres, however, the error of the fugacity calculated by the rule ranges from zero to 20%, depending on the mole fraction. At 100 atmospheres the errors range from zero to about 100%.

THE HYDRATION OF SODIUM MONOMETAPHOSPHATE IN ALKALINE SOLUTION AT 75°. PHOSPHATE V

BY SAMUEL J. KIEHL AND HARRY P. COATS

RECEIVED JUNE 3, 1927

PUBLISHED SEPTEMBER 2, 1927

Introduction

For almost a century it has been known through the work of Graham¹ that the phosphates, ortho-, pyro- and meta-, can be transformed from one to the other. His work at the time was an epoch-making contribution to the chemistry of phosphates, where even today it occupies a remarkably authoritative position.

During the intervening period attention has been directed more especially to the study of the orthophosphate and orthophosphoric acid, with a result of numerous, extensive and valuable researches. The chemistry of the meta- and pyrophosphates has not been as widely nor as satisfactorily developed. The nature of their inter-transformations and the conditions which influence them have been studied more particularly from the standpoint of the rate of hydration and the formulation of it.² To a limited extent the effects of concentration of acid and temperature upon the rate of hydration have been quantitatively investigated.³

No work, moreover, of a definite character has been done on the hydration of the metaphosphate in an alkaline solution. The lack of methods for determining the meta- and pyrophosphates has doubtless retarded the work in this range. The difficulty of obtaining containers which were unaffected by the alkaline solution has possibly contributed to the delay.

In the work which follows, a study of the alkaline hydration of sodium monometaphosphate to sodium pyrophosphate and sodium orthophosphate was undertaken. Pure silver flasks were used as containers. A method of separating and determining pyrophosphate in the presence of ortho- and metaphosphates was employed in following the progress of the hydration of metaphosphate to pyrophosphate. A method of separating

and determining orthophosphate was employed in following the progress of the hydration of metaphosphate to orthophosphate. The results of the investigation are given below.

Apparatus

Bath.—An oil-bath, sensitive to ± 0.01 at 75° , was used. The regulator was a twelve-foot, quarter-inch steel tube, entirely filled with mercury, coiled within the bath. This made and broke in the usual manner an electrical circuit by which the heating current was supplied.

Flasks.—The hydrations were studied in a silver vessel whose capacity was a little over a liter, constructed somewhat after the style of an Erlenmeyer flask. The stopper, made of silver, was ground to fit. Two silver tubes, for the removal of samples, extended through the stopper—similar in the arrangement to an ordinary wash bottle. These tubes were closed with silver plugs ground to fit. As a further precaution against evaporation, the stopper was sealed to the flask with a wax made of one part paraffin and one part carnauba wax. A piece of rubber tubing, closed at one end, was placed over each of the plugs and tubes.

Preparation of Materials

Sodium Monometaphosphate.—Sodium monometaphosphate was prepared by the method previously described.⁴ The dihydrate was obtained when the salt was further purified by thrice crystallizing it from distilled water. By drying it overnight at 100° in a Freas oven the anhydrous salt was prepared. Analyses were made for any remaining water, whereby the necessary corrections were made when and where they were required.

In order to determine if crystallization from water and subsequent heating at 100° would change the character of the salt heretofore described, qualitative tests were made and freezing-point depressions measured. Neither procedure indicated that the salt possessed properties different from those of the salt crystallized from fusion.

The water of hydration was determined by selecting a few large, quickly-dried crystals and finding the loss of weight by ignition. The following results were obtained.

TABLE I
ANALYSIS FOR WATER OF HYDRATION

Samples	No. 1	No. 2
Grams of crystals.....	1.8858	1.9217
Grams of anhydrous salt.....	1.3940	1.4189
Grams volatilized.....	0.4918	0.5028
Percentage of water of hydration.....	26.08	26.17
Percentage of water of hydration (theoretical)....	26.10	

Calculations gave results which corresponded to the formula $\text{NaPO}_3 \cdot 2\text{H}_2\text{O}$.

The following crystallographic measurements were made by Professor Paul Kerr of the Geology Department in Columbia University. "The crystals are triclinic with the following angular measurements between faces:

⁴ Beans and Kiehl, *THIS JOURNAL*, 49, 1878 (1927).

TABLE II
CRYSTALLOGRAPHIC MEASUREMENTS

Faces		Angles measured	
001	100	64°	16'
100	010	73°	28'
010	110	42°	53'
100	110	62°	55'
001	010	82°	33'

"There is a perfect cleavage parallel to (001). On removal from the solution for measurement the crystals soon acquire a white powdery coating which darkens the reflection signals on the goniometer considerably and reduces the accuracy of measurement.

"The mean index of refraction is 1.400 and the double refraction is about 0.009. The material is biaxial with a large axial angle and one of the optic axes is nearly perpendicular to the cleavage (001). The acute bisectrix of the optic angle corresponds to γ , the slow ray, in dispersion $p > v$."

Sodium Pyrophosphate, $\text{Na}_2\text{P}_2\text{O}_7 \cdot 10\text{H}_2\text{O}$.—Normal sodium pyrophosphate was crystallized three times from distilled water and carefully dried.

Disodium Orthophosphate.—Disodium orthophosphate was prepared and the product standardized by the method described by Hansen and one of us.⁵

Sodium Hydroxide.—Solutions of sodium hydroxide used for hydration were made from a saturated solution of the purest available sodium hydroxide. This solution was filtered through a dry filter paper and diluted to a convenient concentration. It was then standardized by Bureau of Standards benzoic acid.

Zinc Acetate Reagent.—Zinc acetate of pure quality, free from phosphate, was used. Eighty grams of the zinc acetate was dissolved in distilled water and diluted to two liters. Two hundred and fifty cubic centimeters of glacial acetic acid were then added. This gave about a 0.2 *M* zinc acetate solution with a hydrogen-ion concentration of 5×10^{-4} moles per liter.

Method of Procedure

Separation of Pyrophosphate from Orthophosphate and the Determination of Pyrophosphate.—In order to determine the extent of hydration in alkaline solution, it was necessary to separate the pyrophosphate formed. After trying many other precipitants, the zinc acetate reagent was found to be the most satisfactory. Orthophosphate gives no precipitate under the conditions described below, except for concentrations greater than 0.1 mole per liter. It, therefore, was successfully used in the separation, even though it did not give a crystalline precipitate, provided the concentration of hydrogen ion was carefully controlled.

Thirty to forty cubic centimeters of zinc acetate reagent was added to the solution containing the pyrophosphate, whose hydrogen-ion concentration was adjusted to 5×10^{-4} moles per liter by the addition of acetic acid and water, thereby making a total of 120 cc. After standing

⁵ Kiehl and Hansen, *THIS JOURNAL*, **48**, 2802 (1926).

for three minutes it was centrifuged for three minutes. The clear liquid was then decanted through a weighed Gooch crucible. Fifty cubic centimeters of distilled water was added with stirring to the precipitate, which was again centrifuged and transferred to the Gooch crucible. Enough 2 *M* sodium hydroxide was added thereafter to dissolve the precipitate on the filter. After dilution to 75 cc. by washings from the filter and Gooch crucible, an equal volume of a solution, so prepared that it contained 4 *M* acetic acid and 0.5 *M* zinc acetate, was added to reprecipitate the pyrophosphate. This solution was centrifuged again and decanted through a weighed Gooch crucible. After decanting the clear solution and one washing with water, the precipitate was transferred to the Gooch crucible with repeated washing, filtered, dried and ignited with a Méker burner for half an hour.

Composition of Ignited Precipitate.—In order to determine whether the precipitated zinc pyrophosphate would give after ignition a product invariable in composition, several quantities of it were prepared and samples from each ignited lot were analyzed. The results of the zinc and phosphorus determinations from two such samples are given below.

Table III shows the amount of zinc found in the ignited precipitate by the potassium ferrocyanide method.

TABLE III
ZINC IN THE PYROPHOSPHATE PRECIPITATE

Sample	G. ppt. taken	G. Zn found
1	0.3026	0.1293
2	.2991	.1278

The phosphorus was determined by the standard gravimetric procedure after complete hydration by boiling with nitric acid. The following values were obtained.

TABLE IV
PHOSPHORUS IN PYROPHOSPHATE PRECIPITATE

Sample	G. ppt. taken	G. $Mg_3P_2O_7$	Equiv. to g. P
1	0.3853	0.2815	0.0784
2	.3286	.2408	.0670

The ratio of atoms of zinc to atoms of phosphorus in the first case is 1 to 0.997, in the second 1 to 0.993. From the percentage of both zinc and phosphorus in the ignited precipitate and from the ratio above, the empirical formula of the ignited zinc precipitate corresponds to $Zn_2P_2O_7$.

In order to determine if the acetic acid used would be sufficient to accelerate the hydration of metaphosphate at room temperature to interfere in the pyrophosphate determination, strong solutions of acetic acid were added to 0.2 *M* sodium monometaphosphate, which was allowed to stand for several days at room temperature. No precipitate with the zinc acetate reagent resulted. Mixtures of sodium acetate, acetic acid, zinc acetate

0.2 *M* metaphosphate and 0.08 *M* orthophosphate, set aside at room temperature for several days, likewise gave no precipitate under the conditions of separation and determination of pyrophosphate.

Determination of Pyrophosphate.—To test the method the following were a few of the determinations which were made on aqueous solutions of sodium pyrophosphate of known value.

TABLE V
PYROPHOSPHATE BY ZINC ACETATE REAGENT

Mg. P taken as pyro-	31.04	31.04	31.04	31.04	31.04
Mg. P found as pyro-	31.05	31.09	31.05	31.08	30.82 30.74
Mg. P taken as pyro-	62.08	62.08	62.08	62.08	62.08 62.08
Mg. P found as pyro-	62.27	61.88	62.10	62.55	61.89 61.85
Mg. P taken as pyro-	153.0	153.0	153.0	153.0	
Mg. P found as pyro-	152.9	153.1	152.8	152.9	

The average deviation in parts per thousand by the above method for the analysis on 31.04 mg. of phosphorus as pyrophosphate is 2; for 62.08 mg. of phosphorus it is 3.

Determination of Orthophosphate in Filtrate.—In the actual hydration after separating pyrophosphate the filtrate contained zinc ion and metaphosphate ion which might offer the possibility of trouble. For assurance it was necessary, therefore, that this filtrate without orthophosphate present give no precipitate under conditions for determining orthophosphate, that metaphosphate be not hydrated in the alkaline solution during the process, and that no precipitate be formed with meta- and orthophosphates present and the magnesia mixture alone absent. Accordingly, no precipitate had formed after standing six days when a portion of plain filtrate without ortho- or metaphosphate present was made alkaline with NH_4OH and treated with the appropriate quantity of magnesia mixture. Likewise, when metaphosphate was added to the plain filtrate and treated as above no precipitate had occurred in fifteen days. Furthermore, with orthophosphate present without the magnesia mixture only, no precipitate had formed during four days.

In the following paragraph the method is outlined for determining orthophosphate in the filtrate from analysis of pyrophosphate in the course of the hydrations.

Sufficient 15 *M* ammonium hydroxide was added to the pyrophosphate filtrate to re-dissolve the zinc precipitate at first formed. Twenty cubic centimeters of 5 *M* ammonium chloride was added. After standing for three hours it was filtered, dissolved and re-precipitated by the standard method in a total volume of 125 cc. After it stood at least three hours it was filtered, ignited and weighed as usual.

Table VI shows some of the determinations of orthophosphate made upon the pyrophosphate filtrate with and without metaphosphate present.

TABLE VI
ORTHOPHOSPHATE IN PYROPHOSPHATE FILTRATE

Mg. P taken as meta-	Mg. P taken as ortho-	Mg. P found as ortho-
388	31.49	33.19
388	31.49	32.45
155	31.49	31.60
155	59.92	60.97
139	14.98	15.42
77	38.80	39.00
77	38.80	38.90
None	31.49	31.48
None	31.49	31.49

Table VII contains a few of the determinations made directly upon orthophosphate solutions with meta- as indicated.

TABLE VII
ORTHOPHOSPHATE DIRECTLY

Mg. P taken as meta-	Mg. P taken as ortho-	Mg. P found as ortho-
217	14.98	15.42
217	59.92	61.03
139	59.92	60.89
77	38.80	38.95
None	59.92	59.47

The values in Tables VI and VII are representative of the many results obtained in testing the method, over the complete range of metaphosphate concentration in the filtrate from the pyrophosphate determination. The average deviation from the amount added is 25 parts per thousand. When tests were made in orthophosphate solutions directly the average deviation was of the order of that from the filtrate of the pyrophosphate with the same amount of metaphosphate present. Inasmuch as the amount of metaphosphate present at any one time did not exceed 140 mg., the average deviation was found from a number of determinations to be 15 parts per thousand.

Test of the Method under Conditions of Hydration.—Whether zinc acetate reagent would precipitate pyrophosphate quantitatively in the concentrations and under the conditions of the hydrations is yet to be demonstrated. Solutions of meta-, pyro- and orthophosphates and sodium hydroxide in concentrations to be found in the hydrations were made at 20° and taken from a buret. These were analyzed for pyro- and orthophosphates. Where 2 *M* sodium hydroxide was used enough glacial acetic acid was added to give a concentration of hydrogen ion of 5×10^{-4} moles per liter.

Table VIII which follows gives the milligrams of phosphorus taken as meta-, pyro- and orthophosphates and the milligrams of phosphorus found as pyro- and orthophosphates.

TABLE VIII
DETERMINATION OF PYRO- AND ORTHOPHOSPHATES

	Molar NaOH	P taken as meta-	P taken as pyro-	P found as pyro-	P taken as ortho-	P found as ortho-

26	None	None	315.00	318.80	None	None
27	None	None	31.00	31.21	None	None

In the above table the average deviation from amount added is 9 parts per 1000 for pyrophosphate and 11 parts per 1000 for orthophosphate.

Experimental Part

The temperature selected for conducting the hydrations was 75°. Solutions were made in a two-liter, calibrated flask with as little contact with air as possible. A sample of each solution was then taken for analysis and for a pycnometric density determination. The remainder was placed in two silver flasks and hydrated in duplicate. The density of each solu-

TABLE IX
SOLUTIONS STUDIED

Soln.	Concn. NaPO ₃ moles per l.	Concn. NaOH moles per l.	Sp. gr. 15.5°/15.5° at beginning	Sp. gr. 15.5°/15.5° at end
A ₁	0.100	0.500	1.031	1.032
B ₁	.200	.500	1.039	1.040
D ₁	.100	2.000	1.093	1.093
E ₁	.200	2.000	1.101	1.101

tion was again determined at the end of each experiment and no change in any case greater than one part in one thousand was observed.

In the beginning from time to time small samples were taken through the silver tubes and tested for pyrophosphate and orthophosphate. When they were found a sample was drawn into a small flask which was quickly stoppered and cooled to 20°. By means of a calibrated pipet 25 cc. was taken and analyzed as described above. The following tables give the percentages of pyrophosphate and orthophosphate found in the solutions at the stated intervals.

In the heading for each table the weight of $\text{Zn}_2\text{P}_2\text{O}_7$ equivalent to the total phosphorus in 25 cc. of solution is given. This we shall call *M*. Similarly the weight of $\text{Mg}_2\text{P}_2\text{O}_7$ will be designated *N*. The calculation of the percentage of phosphorus transformed to pyrophosphate and orthophosphate, respectively, becomes simple when the amounts of $\text{Zn}_2\text{P}_2\text{O}_7$ and $\text{Mg}_2\text{P}_2\text{O}_7$ are actually known for each 25cc. portion.

Discussion of Results

In the alkaline hydration of sodium monometaphosphate, and under the conditions of our experiments, both orthophosphate and pyrophosphate are formed. This was shown by the analyses of the solutions. It was further shown by crystals that separated from the completely hydrated solutions. When these completely hydrated solutions were allowed to stand for several days at room temperature, sodium pyrophosphate

crystallized. The large crystals could be separated easily and washed free of mother liquor and analyzed. If, however, some of the completely

hydrated solution was allowed to evaporate at room temperature, at first sodium pyrophosphate only crystallized. When the solution became more concentrated orthophosphate crystallized also. When both types of crystals were carefully freed from the mother liquor and dried, the

sodium orthophosphate crystals became visibly efflorescent within a few hours, while the pyrophosphate crystals remained unchanged. These

efflorescent crystals were separated from the others and tested. They were orthophosphate crystals.

Since orthophosphate and pyrophosphate were both found when the

metaphosphate was completely hydrated, and since they appeared in each hydration to reach a final value of approximately 34% of the phosphorus in the form of orthophosphate, it would seem that the pyrophosphate and orthophosphate were either end-products or in equilibrium with each other.

That orthophosphate and pyrophosphate were not in equilibrium was shown by the following experiments:

A duplicate of Hydration B was kept in the 75° bath for 419 hours after the metaphosphate had disappeared. No change in the ratio of pyrophosphate to orthophosphate was found. The solution was then placed in the 100° bath and analyzed from time to time for 414 hours more. There was no change in the ratio of pyrophosphate to orthophosphate.

In the D and E hydrations four times as much sodium hydroxide was used as in the A and B hydrations, but the final ratio of pyrophosphate to orthophosphate was the same.

A solution called C, containing 0.5 *M* sodium hydroxide and 0.1 *M* disodium orthophosphate, was kept in the 75° bath for seven days without producing any pyrophosphate.

Another solution, called F, was made of 2.0 *M* sodium hydroxide, and 0.1 *M* phosphorus as ortho- and pyrophosphates. Twenty-five per cent. of the phosphorus was in the form of normal sodium pyrophosphate and 75% disodium orthophosphate. It remained in the 75° bath for 23 days without any orthophosphate reacting to form pyrophosphate, or pyrophosphate to form orthophosphate.

Another solution, called G, was made of 0.2 *M* phosphorus in the form of ortho- and metaphosphates with 2.0 *M* sodium hydroxide. One-third was sodium monometaphosphate and two-thirds disodium orthophosphate. This was kept in the boiling bath for 22 days. The pyrophosphate obtained was that which would result from the hydration of the monometaphosphate added as shown in the preceding tables while the orthophosphate was increased by 34% of the amount of phosphorus added as monometaphosphate. No orthophosphate was transformed to pyrophosphate.

In order to determine if pyrophosphate would hydrate to orthophosphate a solution of 0.2 *M* sodium pyrophosphate and 2.0 *M* sodium hydroxide was kept in the boiling bath for 22 days without a trace of orthophosphate being formed.

A 0.2 *M* sodium pyrophosphate in a 4.0 *M* sodium hydroxide solution was kept in the boiling bath for four days. No orthophosphate was produced.

Since neither increase of temperature nor change of concentration of phosphates and sodium hydroxide altered the ratio of pyrophosphate to

orthophosphate, and since pyrophosphate was not formed from orthophosphate in solution, and since orthophosphate was not formed from pyrophosphate, it seemed reasonably certain that no equilibrium existed under the conditions of our experiments.

All of these experiments were carried out in pure silver flasks.

Graham⁶ states: "But pyrophosphate of soda may be boiled with caustic soda for hours without sensible alteration, provided the solution is not evaporated to dryness; and it crystallizes afterwards in its original form, exhibiting no disposition whatever to form sub-pyrophosphate."

Therefore, since the orthophosphate did not appear from the hydration of pyrophosphate, it must have been produced by the hydration of metaphosphate, and since the pyrophosphate which was present in the hydrations did not result from the dehydration of orthophosphate, it must have occurred from the hydration of the metaphosphate.

It is of interest to note that the orthophosphate and the pyrophosphate were produced in equimolecular quantities. From our work it seems that for every three moles of the sodium monometaphosphate hydrated one mole of orthophosphate and one mole of pyrophosphate were produced simultaneously.

This may mean two independent reactions or one single involved reaction; but since the experimentation has not covered a wide enough range of temperature the decision cannot be made. However, one may conceive of the possibility of two different rates of hydration, if there are two reactions, each affected to a different degree by temperature. Work is planned to elucidate the mechanism and clear this point.

The foregoing experimental data and Figures 1, 2, 3 and 4 demonstrate that an increase in the hydroxyl-ion concentration increases the rate of hydration.

Summary

1. Sodium monometaphosphate dihydrate was prepared.
2. A method of determining pyrophosphate in the presence of meta- and orthophosphate was developed.
3. Sodium monometaphosphate was hydrated to sodium pyrophosphate and sodium orthophosphate in alkaline solution at 75° in silver flasks.
4. Sodium pyrophosphate is an end-product and sodium orthophosphate is an end-product, in the alkaline hydration of sodium monometaphosphate when reactions are carried out in silver flasks.
5. The increase of the sodium hydroxide concentration increased the rate of hydration.

THE ACTION OF LIGHT ON CHLORINE

By GEORGE B. KISTIAKOWSKY¹

RECEIVED JUNE 16, 1927

PUBLISHED SEPTEMBER 2, 1927

I. Introduction

A comparison of the photochemical literature on the reactions and other properties of illuminated chlorine on one side and of the results of a more physical investigation of its absorption spectrum on the other, indicates that, at present, a certain controversy exists between two main opinions on the nature of the primary action of light on chlorine.

Several studies of the absorption spectra of the halogens, of the more recent ones particularly that of Kuhn,² demonstrated the existence of series of absorption bands converging on the short-wave side to a limit, from which a continuous absorption extends toward the ultraviolet. On the basis of these observations Franck³ suggested that chlorine and other halogen molecules are dissociated into atoms—a normal and an excited atom—on absorption of radiation frequencies belonging to the continuous absorption region and that absorption in the region of the band spectrum causes formation of activated molecules, capable in general of reëmission of absorbed light energy as fluorescence radiation. Franck's conclusions were later confirmed by Dymond⁴ who showed that fluorescence is emitted by iodine molecules only on absorption of light of longer wave length than 5000 Å.—the convergence limit of this halogen. It may be pointed out that, according to physical researches, a further condition for the realization of fluorescence in halogen vapors is their low pressure. Thus, Wood and Speace⁵ found that excited iodine molecules can be deactivated on collisions not only in presence of foreign gases but also in pure iodine vapor.

A number of different theories on the nature of the primary action of light on chlorine have been advanced recently by several photochemists, their common experimental basis being the observation of Coehn and Jung⁶ that a pure and dry mixture of chlorine and hydrogen does not react on illumination by visible and near ultraviolet light. The theory of Norrish,⁷ however, who located the chemical action of light on chlorine in the water-chlorine film on the walls of the containing vessel, has been recently disproved by decisive experiments of Coehn and Heymer.⁸ Fur-

ther, primary formation of activated chlorine molecules⁹ or of chlorine atoms⁶ has been occasionally suggested, the catalytic action of water being attributed to secondary processes. These theories coincide, at least in broad terms, with the deductions from the study of the absorption spectrum of chlorine, since, as Franck³ pointed out, dissociation into atoms must be preceded by activation of chlorine molecules. Only further investigations can decide to which of these stages the photochemical reactivity of chlorine should be attributed. A distinctly different theory has been advanced by Weigert,^{10,11} who suggested that water molecules are necessary for the accomplishment of the *primary* photochemical process in chlorine. If this latter is absolutely pure, all absorbed light energy is reëmitted by chlorine molecules as isochromatic fluorescence and only in presence of water or certain other molecules can the absorbed radiation be converted into chemical energy or into heat. The special nature of this action of foreign molecules was also discussed by Weigert and he suggested for instance that, in the hydrogen-chlorine reaction, water acts through its di-pole nature, facilitating an inner photo-electric effect between hydrogen and chlorine. As an important support of his theory Weigert cited the results of investigations on the Budde effect—the expansion of chlorine gas on illumination. Since Budde's¹² discovery, more recent investigations have demonstrated that the effect is due entirely to the conversion of absorbed light energy in chlorine into heat.^{13,14} Further, it was found that *dry* chlorine shows a very small Budde effect and that the effect can be increased considerably by admission of some moisture to the gas.¹⁵ Ludlam¹⁶ arrived at a similar conclusion, experimenting with bromine.

In the opinion of Weigert this observed absence of the heating of dry chlorine is a direct evidence that the absorbed light energy can be converted into heat only in presence of moisture and is reëmitted as fluorescence by pure gas. Lewis and Rideal¹⁷ went even further. On investigating the Budde effect in bromine vapor, they suggested that only a definite molecular compound $\text{Br}_2\text{-H}_2\text{O}$ is photosensitive and that all light absorbed by simple bromine molecules is re-radiated again as fluorescence.

Summarizing, it may be pointed out that all theories which assume the presence of foreign molecules to be necessary for the primary photo-

chemical process assume at the same time that pure chlorine (and similarly bromine) does fluoresce. With the test of this latter conclusion we are concerned in the experiments now to be described.

II. Experimental Arrangement

In order to obtain gas of a known photochemical inactivity the method of Coehn and Jung⁶ of purification and drying of chlorine was closely followed. The apparatus consisted of a distilling arrangement for chlorine, of a quartz spiral manometer (quartz-Pyrex graded seal being used) and of two cylindrical vessels 23×3.5 cm. with sealed-on, optically clear Pyrex glass plates. These latter were necessary since, in search of chlorine fluorescence, all light from the illuminating source scattered on glass surfaces should be avoided as far as possible. The process of sealing-on proved to be not very difficult and although the edges of the plates were slightly damaged, their middle areas of about 2 cm. diameter remained entirely intact. Each vessel had two side tubes, one of which contained an inner glass seal separating a small volume (about 0.75 cc.) filled with water vapor at atmospheric pressure, the other being used for freezing out chlorine in some of the experiments. Stopcocks in the part of the apparatus behind the high-vacuum pump were entirely avoided; instead, inner glass seals operated by iron cores (enclosed in glass) and constriction for sealing-off were used. The whole apparatus, including the manometer, was baked out in a vacuum¹⁸ on two successive days, the test for tightness being that the pressure in the McLeod gauge did not increase overnight to more than 10^{-6} mm. The mercury-vapor trap was cooled by liquid air only during the second baking out and subsequent operations.

Chlorine from a half-empty chlorine tank was three times distilled in a vacuum at -112° (the temperature of melting carbon disulfide). Each time only about three-fourths of the chlorine was distilled over, the rest being sealed off. Finally, chlorine was condensed in the side tubes of the cylindrical vessels and these were sealed off from the rest of the apparatus. Of three attempted fillings only two could be carried out successfully. The first time chlorine of about 500 mm. pressure was prepared and preliminary measurements were taken. These results, although less exact, confirm entirely the final experiments with the third filling and chlorine of about 2 atmospheres' pressure.

III. Absorption of Light in Moist and Dry Chlorine

It may be concluded from Kuhn's² description of his experimental arrangement that he worked with fairly dry chlorine. It appeared to be of interest, nevertheless, to measure the wave length of the bands' convergence limit in the available chlorine of highest purity. For photographs of the chlorine absorption spectrum a Hilger glass spectograph, with a large direct vision prism inserted to increase the dispersion, was employed.¹⁹ Since the chlorine layer used was only 23 cm. long, the light absorption in the green was very weak even at 2 atmospheres' pressure. Therefore, the measurement of single bands with subsequent calculation of the convergence limit had to be abandoned. Still, study of the plates with a micrometer, as also curves made on the densitometer, permitted

¹⁸ For details compare Dushman, *High Vacuum Technique*, *Gen. Elec. Rev.*, Schenectady, 1922.

¹⁹ The author is indebted to Professor A. Shenstone of the Department of Physics for his kind advice and help during this part of the work.

an approximate determination of the convergence limit at 4790 Å. The reference spectrum used was that of an iron arc. The accuracy of this determination is about 10 Å. (1 mm. on the plates), so that the result obtained is to be considered identical with Kuhn's more exact value 4785 Å. Determinations of absorption coefficients of chlorine in monochromatic light of different wave lengths were carried out with unusual precision by Halban and Siedentopf.²⁰ They studied also the influence of moisture and found in light of three different wave lengths no appreciable difference between moist and fairly dry chlorine. A question which is not decided by these experiments and which is of importance for the following discussion is whether the total absorption in polychromatic light is markedly different in very dry and in moist chlorine. For the following measurements the glass vessels containing chlorine were placed in a blackened box with two openings rigidly adjusted on an optical bench. As light source a 100-watt Pointolite lamp was used, which in order to increase the intensity of shorter wave lengths was overloaded and burned on 1400 m. amps. and 115 volts. A system of lenses and diaphragms isolated a parallel beam of light, the square section of which was about 2.5 sq. cm. Immediately behind the chlorine vessel was placed a Moll thermopile of surface (3.14 sq. cm.) larger than the area of the light beam. The only light filter used for these and later experiments was a concentrated solution of ferrous sulfate (and a small quantity of hydrazine sulfate) which absorbed infra-red and a part of the extreme red radiation. Table I gives the results of measurements with chlorine of two atmospheres' pressure.

TABLE I
LIGHT ABSORPTION IN CHLORINE; PER CENT. OF THE TOTAL RADIATION

Dry chlorine	8.45; 9.95; 8.22; 8.40; av. 8.75
Moist chlorine	9.89; 7.91; av. 8.90

Each of these values is an average of about 20 single readings, half of them with the vessel filled with chlorine, half with the empty vessel, chlorine being frozen out by liquid air. The deviations of the values given are rather large—10% and more from the final averages. They are due not to the inexactness of the thermopile readings, but to the impossibility of keeping the light intensity constant to more than 1-2% during the longer time intervals necessary for freezing out and warming up of chlorine and eventually of water, this being admitted to the chlorine by breaking the inner glass seals mentioned earlier.

IV. Fluorescence of Dry Chlorine

The optical arrangement described in the former section was used also for the study of chlorine fluorescence. This part of the work included

²⁰ Halban and Siedentopf, *Z. physik. Chem.*, 103, 71 (1923).

experiments with the thermopile and spectrophotographic tests. The determination of the light absorption in chlorine was carried out with the sensitivity of the thermopile-galvanometer system reduced to 7.15% by series and shunt resistances. In order to test this calculated ratio of sensitivities, the light intensity of a special standard lamp was measured with full and reduced sensitivity. The ratio of scale deflections so determined was practically identical with the calculated, 0.073. The thermopile with full sensitivity of the circuit was placed at a distance of 1 cm. from the side wall of the chlorine vessel at a right angle to the light beam. Assuming a uniform distribution of fluorescence over the hypothetical radiating surface (of which the thermopile is a part) (399 sq. cm.), 0.0082 of the total emitted radiation should fall on the light sensitive surface of the thermopile. This calculation is somewhat unfavorable, since the thermopile was put close to that end of the vessel where the light beam entered and a greater part of the fluorescence should be concentrated here on account of the greater light absorption in the initial layers of chlorine. Further, in front of the thermopile was a polished metallic cone of 1 cm. length and 4 sq. cm. open front surface. If all light falling on the side walls of the cone was reflected to the light-sensitive surface of the thermopile, then the above fraction should be increased to about 0.013. The scale deflection corresponding to the light energy absorbed by chlorine was on the average 16.1 mm. (with reduced sensitivity). Thus, if all the light absorbed is reëmitted by dry chlorine as fluorescence, a deflection of at least 1.85 mm. should be expected. Measurements with the vessel filled with chlorine and with the empty vessel yielded 0.43 and 0.31 mm., respectively, as averages of about 20 single readings for each value. The single readings fluctuated between -0.1 and $+0.7$ mm.

There were good grounds for believing that even these small deflections—their difference ("the fluorescence") does not amount to more than 5% of the calculated value—are due to some heating effects on illumination rather than to emission of visible light, since, on visual observation, the chlorine vessel remained entirely dark when the light beam was passed through it.

The Hilger spectrograph, without the additional prism and with the slit wide open, was adjusted in the box at right angles to the light beam and at 2 cm. distance from the side walls of the chlorine vessel. Photographs taken with exposures of from one to six hours and with the vessel filled with chlorine or empty showed in no case even the slightest trace of spectrum image. On the other hand, when the spectrograph was placed behind the chlorine vessel in the path of the light beam, with a ground glass plate in front of the slit at a distance of 2 cm., a well-developable image of the spectrum was obtained even after an exposure of one second.

From these data it is easily calculable that the fraction of absorbed light energy which is reëmitted as fluorescence by dry chlorine must be considerably smaller than the upper limit of 5% determined by means of the thermopile.

V. Discussion

The results of the experiments described are these: the structure of the absorption spectrum and the total absorption of chlorine are not appreciably changed by extreme drying; only an extraordinarily small fraction of the absorbed light energy can be reëmitted as fluorescence even in very dry chlorine. On the other hand, there is little doubt as to the reality of the decrease of the Budde effect on drying chlorine. These observations of different investigators seem to contradict each other. Evidently, since fluorescence is absent and the extent of absorption is unchanged, it must be concluded that one and the same amount of light energy introduced may or may not cause a heating effect, depending only on the presence or absence of impurities in chlorine.

It is rather difficult to reconcile the new data with the theories of Weigert and others who assume that, for the primary photochemical process in chlorine, the presence of foreign molecules is necessary. The absence of fluorescence and their denial of the dissociation of "free" chlorine molecules leave no choice but the conclusion that the absorbed light energy is converted by these "free" molecules into heat, and this is in strict disagreement with the observations on the Budde effect. An assumption that the absorbed light energy is somehow stored up (in absence of water) in activated chlorine molecules, an assumption rather improbable in itself, is further decidedly disproved by experiments of Bodenstein and Taylor²¹ and of Marshall²² on the life of activated chlorine.

The difficulty in reconciling the existing data is not entirely removed by accepting the theory that the primary photochemical process in chlorine is, independently of the presence of impurities, a dissociation into atoms. Since under these circumstances the process which contributes to the warming up of the illuminated gas would be almost entirely the recombination of chlorine atoms to molecules, it must be assumed that, in absence of water molecules, this process is very slow in the gas phase and takes place almost exclusively on the dry walls of the containing vessel. Thus, the absorbed light energy will be transported to the walls and cannot cause the Budde effect on account of the large heat capacity and relatively good heat conductance of the glass walls. The experiments described give, of course, no indication as to the nature of the catalytic action of water on the rate of recombination of chlorine atoms.

A certain difficulty with the explanation of the Budde effect here ad-

²¹ Bodenstein and Taylor, *Z. Elektrochem.*, 22, 202 (1916).

²² Marshall, *J. Phys. Chem.*, 30, 757 (1926).

vanced arises from the thermodynamic consideration that in such a case the rate of thermal dissociation of chlorine molecules should also be accelerated by water vapor.

Summary

1. A brief account of theories on the nature of the primary photochemical process in chlorine has been given.

2. Earlier measurements and the data now obtained show that extreme drying of chlorine does not change appreciably either the structure of its absorption spectrum or the total amount of light energy absorbed.

3. Measurements of a possible fluorescence in dry chlorine reveal that certainly less than 5% of the absorbed light energy is reëmitted as fluorescence.

4. It has been suggested, in order to reconcile these experimental results with the known influence of moisture on the Budde effect, that chlorine (or other halogen)² is dissociated into atoms on absorption of light energy in the region of continuous absorption independently of its degree of purity; water is assumed to have a catalytic influence on the rate of recombination of the atoms and, therefore, also on the rate of thermal dissociation of chlorine molecules.

HEATS OF ADSORPTION ON POISONED AND HEAT-TREATED CATALYSTS

BY GEORGE B. KISTIAKOWSKY,¹ EARL W. FLOSDORF, AND HUGH S. TAYLOR

RECEIVED JUNE 18, 1927

PUBLISHED SEPTEMBER 2, 1927

In the preceding five years the non-uniform character of the catalyst surface has been developed by quantitative studies of adsorption, reaction kinetics, poisoning and promoter action on a variety of catalysts. This differentiation in the catalytic activities of the units in the catalyst surface has permitted an experimental attack on the problem of activation at the catalyst surface, a most important step in placing the study of contact catalysis on a scientific basis and in freeing catalysis from the bane of empiricism.

Experiments by Gauger² and by Wolfenden³ on the ionization potentials of adsorbed hydrogen on hydrogenation catalysts have indicated that the hydrogen adsorbed on the more active portions of a catalyst surface may be atomic. These experiments were extended by Kistiakowsky⁴

¹ International Research Fellow.

² Gauger, *THIS JOURNAL*, **46**, 674 (1924).

³ Wolfenden, *Proc. Roy. Soc. (London)*, **110A**, 404 (1926).

⁴ Kistiakowsky, *J. Phys. Chem.*, **30**, 1356 (1926).

to ammonia-making catalysts, with the result that evidence for the presence of both atomic nitrogen and hydrogen was obtained. A series of investigations with the problem of activation as the objective is also in progress in Princeton, the heat of adsorption of the gas being the measure of activation. The work of Beebe and Taylor⁵ showed that the integral heat of adsorption of hydrogen on nickel and copper was of the order of 10,000–20,000 calories, greatly in excess of the heat of liquefaction, and variable with varying preparations of catalyst. Fryling⁶ elucidated this variable behavior by a study of promoted nickel catalysts, showing, in addition, that on active promoted catalysts the curve for the heat of adsorption with increasing adsorption gave initially low values, next a maximum and then decreasing heats of adsorption. Fryling attributed the initial rise in the curve to an activation of the adsorbed hydrogen molecules, the heat measured being a composite of a positive heat of adsorption and a negative heat of activation. Fryling assumed that, in the limit, this activation consisted in a dissociation into hydrogen atoms

As pointed out by Taylor,⁷ on the assumption of a dissociation into atoms, from the initial heat of adsorption at very low partial pressures a value of the heat of adsorption of hydrogen atoms can be deduced and hence a more penetrating analysis of the possible stages in a contact catalytic hydrogenation or dehydrogenation process may be secured. To study these limiting values of adsorption heats a more exact experimental technique has been developed⁸ which permits the measurement of the heat of adsorption of a few tenths of a cc. of gas on 100 g. of a catalyst. We have reported the results of such a study elsewhere, using a sample of reduced copper as adsorbent and both hydrogen and carbon monoxide as adsorbates. In the case of hydrogen, an active catalyst and one poisoned with oxygen were studied. The active catalyst showed a maximum in the curve similar to that reported by Fryling on nickel. Poisoning the catalyst with oxygen eliminated this maximum. In the case of carbon monoxide as adsorbate, the initial gas adsorbed showed high values, which fell as adsorption proceeded to a minimum value, the amount there adsorbed corresponding identically to the position on the hydrogen curve where a maximum was shown. The carbon monoxide heat of adsorption then showed a further increase to a maximum and subsequently a steady decrease. Kistiakowsky has shown⁹ that all these results are in agreement with a modified Langmuir theory of gas adsorption in which the surface shows varying types of "elementary spaces"

on some of which activation as well as adsorption of the gas molecules can occur, whereas on the remainder adsorption alone occurs.

Earlier studies of metallic catalysts¹⁰ have shown that their sensitivity to heat treatment was much more pronounced when catalytic activity instead of adsorptive capacity was used as the criterion of sensitivity. Thus, Pease showed that a 70% decrease in hydrogen adsorptive capacity and a 22% decrease in ethylene adsorptive capacity, at 1 atmosphere, were accompanied by a decrease in catalytic activity amounting to 85%. Such results pointed to the importance, for catalytic activity, of the strong or low-pressure adsorption, a conclusion which the poisoning studies abundantly confirmed. The new technique now available for measurement of heats of adsorption of small amounts of gas at very low partial pressures permits a reëxamination of the problem from the standpoint of heats of adsorption, and yields, as is shown in the following pages, abundant confirmation of this conclusion and a further development of our ideas concerning activation in its dependence on the nature of the catalyst surface. We have examined the heats of adsorption of hydrogen on an active copper catalyst and on the same catalyst after two successive reductions in activity by suitable heat treatment. For purposes of comparison we also record our earlier results with poisoned copper.

Experimental

The heats of adsorption were measured in a special glass vacuum calorimeter which has already been described in detail elsewhere.¹¹ The apparatus used in these studies was unchanged save that the dead space in the apparatus outside the calorimeter was still further reduced with the object of increasing the accuracy of the adsorption measurements. We do not, however, estimate the accuracy any higher than that previously claimed, namely, 10%; on the most important portions of the curves, below 3 cc. of adsorbed gas, we believe the accuracy is higher than this. But a 10% accuracy is adequate for all the conclusions that we shall draw from the results. In the earlier work we may have overestimated the accuracy of the measurements at the end of the curve where 80% of the gas admitted is not adsorbed. Since this part of the curve (> 8 cc. adsorbed) is not of interest in the present study, we have not pursued the measurements in this region with sufficient care to state any definitive results. The details of the measurement of heats of adsorption, extent of adsorption and of the heat capacity of the calorimeter have already been given¹² and will not be repeated here.

Catalysts Employed.—Measurements have been made on a sample of copper obtained by reduction of a high grade of copper oxide granules.

¹⁰ Pease, *THIS JOURNAL*, 45, 2296 (1923).

¹¹ Ref. 8, p. 352.

¹² Ref. 8, p. 353.

The reduction was carried out very slowly with hydrogen gas at a temperature of 160° over a period of weeks, and gave us a sample (No. 1) of high catalytic activity and adsorptive capacity. To obtain the less active preparations this catalyst was subjected subsequently to two successive heat treatments, the first at 250° for 30 hours in a vacuum, the second to 300° for a period of 8 hours. The sample after these two treatments is designated as No. 2 and No. 3 in the experimental results. On the catalyst in each state, measurements were made of the heat of adsorption of successive increments of 0.3–0.4 cc. of hydrogen up to 8 cc. adsorbed.

Experimental Results.—The experimental data thus secured are shown graphically in Figs. 1 and 2. In Fig. 1 are recorded all the experimental

Fig. 1.—Heat treatment. 1.—● 160° ; 2.—● 250° (30 hrs.); 3.—○ 300° (8 hrs.).

data on the heats of adsorption of the catalyst in its three states of preparation. Fig. 2 records the pressure and adsorbed amount before and after the first heat treatment.

In regard to heats of adsorption, the experimental results are exactly what would be expected from our previous experience with such catalysts and from the theory of the catalytic surface developed in Princeton. The most active preparation (Fig. 1, No. 1) shows the most pronounced maximum in the curve and a maximum at a point corresponding to 1.5 cc. of adsorbed gas. The first heat treatment reduces the heat developed at the maximum and also decreases the amount adsorbed at the maximum to 1 cc. The second heat treatment eliminates all evidence of a maximum. We interpret these results as indicating in the active preparations a greater fraction of the surface capable of activating the adsorbed species,

the activation process being endothermic and, possibly, a dissociation into atoms. The heat treatment destroys these active areas on the surface preferentially.

That the destruction of these areas may be without marked influence on the *total* adsorption is evident from Fig. 2. The curves show that the pressure at which a small amount of gas is adsorbed is markedly less with the active preparation (1) than with the heat-treated catalyst (3).

Fig. 2.—Pressure and adsorbed amount before and after heat treatment.

Heat treatment destroys the surface which adsorbs at low pressures. Beyond 8 cc. of adsorbed gas, however, the curves cross each other and, in this case at least, the heat-treated catalyst displays in the region 8–12 cc. adsorbed (20–100 mm. pressure), a higher adsorption at a given pressure. It is possible, however, that these curves might again cross each other at higher gas pressures. Our experimental set-up in this study was not suited to such measurements, but other data in this Laboratory suggest its probability. We see in such complex adsorption isotherms the best possible evidence of a surface of "variable elementary spaces,"

the distribution of which may vary widely between the extremes of most active and least active.

In Fig. 3 we record the results of an earlier study of an active copper catalyst before and after poisoning with oxygen. The active catalyst (No. 1) is seen to be in every way similar to that in Fig. 1; the poisoning with oxygen destroys the maximum in the curve and gives a curve (No. 2) which we regard as typical of adsorption without activation. This is in accord with our concept that poisons are preferentially adsorbed on the active areas.

Fig 3.—Oxygen treatment.

Theoretical

A difficulty of theoretical importance in connection with these results on the heat of adsorption on active catalysts may now be stated in the hope that some suggestions may be forthcoming as to its solution. It has been pointed out to us by Professor K. Herzfeld of Johns Hopkins University that, with the active preparations, the process first occurring is one in which the decrease in internal energy is very much less than that occurring subsequently at the maximum point and beyond. There is no evidence that the entropy changes involved would cause the free energy decrease at low absorptions to be greater than those obtaining at the maximum. The problem therefore arises as to why the process with a smaller free energy decrease should occur preferentially to that in which the larger free energy decrease can take place. It is known, of course, that change in free energy is not a measure of reaction velocity in many chemical reactions. Does the same hold true in processes of adsorption?

Summary

Measurements of the heat of adsorption of hydrogen on active and heat-treated copper catalysts have been made.

The active preparations show maxima in the curves of heat of adsorption plotted against amount adsorbed.

With partially de-activated catalysts the maximum occurs when smaller amounts of gas are adsorbed. Further de-activation eliminates such maxima.

These results are in harmony with a theory of the catalytic surface with variable elementary spaces, upon the most active of which adsorption is accompanied by an endothermic activation process.

THE DENSITY OF SOLUTIONS OF SODIUM IN LIQUID AMMONIA

By CHARLES A. KRAUS, E. SEATON CARNEY AND WARREN C. JOHNSON

RECEIVED JUNE 18, 1927

PUBLISHED SEPTEMBER 2, 1927

According to Kraus and Lucasse¹ the density of a concentrated solution of sodium or potassium in liquid ammonia is markedly lower than that of either of its components, which shows that the process of solution of these metals is accompanied by a large increase in volume. Forney² investigated the density of solutions of sodium in liquid ammonia at higher concentrations, using for this purpose a specially designed spring balance. This method, however, did not prove sufficiently sensitive to admit of accurate determination of the volume change. Since these solutions are very exceptional in their behavior, it was thought worth while to develop a method whereby their density could be determined with a relatively high degree of accuracy. An apparatus was therefore designed whereby the density was measured directly by means of a Westphal balance.

Apparatus and Procedure

The chief difficulty encountered in determining the density of solutions of the alkali metals in liquid ammonia is due to their extreme reactivity toward oxygen and moisture. This was overcome by maintaining an atmosphere of hydrogen over the solutions during the course of the measurements. The essential features of the apparatus are shown in outline in Fig. 1. The balance, which was equipped with suitable clamping and leveling devices, was placed in a sealed case provided with plate glass windows on opposite sides. Special riders were constructed of inverted "U" form, carrying a loop at the top. The riders were manipulated

¹ (a) Kraus and Lucasse, *THIS JOURNAL*, **43**, 2538 (1921); (b) *ibid.*, **44**, 1941 (1922).

² Forney, *Thesis*, Clark University, 1923.

from without the case by means of a rider carrier A. A hook B was

provided within the case on which the riders were placed when not in use. The beam could be fixed in position by means of the clamps CC. The balance case was connected to the density tube D by means of a short length of rubber tubing E. A special bob F was constructed of Pyrex glass and adjusted to have a volume of 5.000 cc. at -33.8° , the temperature at which the density measurements were carried out. The density of the solutions could thus be read directly in terms of the position of the riders on the beam. The beam was connected to the bob by means of a silk thread G, which passed through the rubber tube E, and which, in turn, was connected to a fine platinum wire H attached to the bob. During the weighing operations, the density tube D, as well as the balance case, was filled with pure hydrogen at a pressure slightly above that of the atmosphere. In general, a slow stream of hydrogen was maintained through the upper portion of the density tube and the case and out through the tube I, which was connected with a mercury trap, not shown in the figure. Except during the weighings, connection between the

Fig. 1.

balance case and the density tube was shut off by compressing the rubber tube E with a small screw clamp.

Sodium was introduced into the bottom of the density tube through a fine capillary by the method of Kraus and Lucasse,¹ the tube being sealed off at J on completion of this operation. The tube K was connected with a source of pure ammonia, a high-vacuum pump, a source of pure hydrogen and a Toepler pump. The procedure used in introducing liquid ammonia into the tube D was similar to that described by Kraus and Lucasse.¹ The volume of the solvent was measured, prior to introduction, by means of pipet cells having a volume of from 2 to 10 cc. and graduated in 0.01 cc.

In making a series of density determinations, the following procedure was employed. After introducing the sodium, the density tube was thoroughly evacuated. It was then surrounded by a bath of ammonia (in a Dewar tube) boiling freely under the pressure of the atmosphere. An electric current was passed through the small nichrome wire coil L for the purpose of maintaining constant ebullition. Liquid ammonia, whose volume had been measured in the pipet cells, was then condensed in the tube D, the ammonia vapor passing through the tubes K and O and the stopcock M. The solution was thus stirred by the vapor passing through it. The stopcock P connected the density tube with the external atmosphere through a mercury trap and wash bottle in which any ammonia carried over was absorbed and later determined by titration. After condensing the ammonia in the density tube, a stream of hydrogen was passed through the stopcock M and tube O for the purpose of stirring the solution until equilibrium was established. Any ammonia carried over with the escaping hydrogen was absorbed in the wash bottle already mentioned and later determined by titration. The screw clamp attached to E was then removed, the balance beam was set free and the density read by means of the Westphal balance. The clamp was then replaced and the hydrogen present in the density tube, together with a small quantity of ammonia which varied with the concentration of the solution, was removed by means of a Toepler pump. The ammonia carried over in this process was absorbed in water and determined by titration. The stopcock N was used for the purpose of equalizing the pressure between the density tube and the auxiliary tube O.

After having removed the hydrogen from the density tube, another measured quantity of ammonia was introduced and the density determined as before. The procedure, as above described, was repeated until the limit of capacity of the density tube was reached.

The ammonia present in the tube was then evaporated and the last trace removed by means of a high-vacuum pump. The tube J was broken off near the tip and the sodium dissolved in a mixture of 50% of absolute alcohol and ether. When the metal was completely dissolved, the solution was allowed to run into a large platinum dish and sulfuric acid was added until it was neutral or slightly acid. The solvent was then evaporated, an excess of acid was added and the sodium finally determined as sodium sulfate.

In order to determine the volume change accompanying the formation of the saturated sodium solution from its components, it was necessary to make a precise determination of the concentration of this solution. This was done by the method of Kraus and Johnson,² a detailed description of which need not be repeated here. It consists essentially

² Kraus and Johnson, *THIS JOURNAL*, 47, 725 (1925).

in measuring the equilibrium pressure for a series of mixtures of sodium and ammonia of known composition. So long as sodium is present in excess, the pressure remains fixed, but as soon as the amount of ammonia is in excess of that necessary for complete solution of the sodium, a rapid rise in pressure occurs. By graphical means the point corresponding to the saturated solution can be evaluated with considerable precision. The pressure measurements were extended to fairly dilute solutions in order to obtain the data necessary for correcting the concentrations, in the density determinations, for ammonia present in the vapor phase.

Results

The density values as obtained are presented in Table I, in which the weight of ammonia in the solution is given in the first column, the number of moles of ammonia per atom of sodium in the second column, the density of the solution in the third column and the volume change per atom of sodium, ΔV , in the last column. The volume change is calculated by means of the equation

$$\Delta V = \frac{N \times 17.032 + 22.997}{D_s} - \left(\frac{N \times 17.032}{D_{NH_3}} + \frac{22.997}{D_{Na}} \right)$$

where N is the number of moles of ammonia per atom of sodium, D_s is the density of sodium at the temperature of the solution and D_{NH_3} is the density of pure ammonia at the same temperature. The reduced barometric reading during the experiment was 742.25 mm. of mercury, which corresponds to a temperature of -33.8° for the boiling point of liquid ammonia.⁴ The density of pure ammonia at this temperature is 0.6824⁵ and that of sodium 0.9805. The latter value was obtained by

In Table II are given the values of the equilibrium pressures as measured for solutions of sodium in liquid ammonia at various concentrations, including saturated solutions.

Fig. 2.

These results presented in Table II are shown graphically in Fig. 2, where pressures are plotted as ordinates against moles of ammonia per

⁶ Dewar, *Chem. News*, 85, 277 (1902).

⁷ Richards and Brink, *THIS JOURNAL*, 29, 117 (1907).

atom of sodium as abscissas. Points of Series 1 are represented by combined crosses and circles and of Series 2 by crosses.

From the plot the composition of the saturated solution of sodium in liquid ammonia was found to be 5.48 moles of ammonia per atom of sodium.

Discussion

The density of solutions of sodium in liquid ammonia is shown as a function of the concentration in Fig. 3, in which densities are plotted as ordinates. In Curve 2, the number of moles of ammonia per atom of sodium are plotted as abscissas, while in Curve 1 the number of atoms of sodium per mole of ammonia are correspondingly plotted. In Fig. 4 values of ΔV are plotted as a function of the concentration expressed in moles of ammonia per atom of sodium.

Fig. 3.

The relative values of the density are consistent with one another within less than two units in the fourth place. This is well illustrated by the ΔV curve (Fig. 4), which is quite sensitive to errors in the density values. The maximum deviation of the values of ΔV , as determined, from those of the smooth curve, as drawn, lies well within an error limit of two units in the fourth place in the value of the density.

The density of the saturated solution has a value of 0.5782 as against 0.6824 for pure ammonia and 0.9805 for sodium. From the determined concentration of the saturated solution, the volume change accompanying the formation of this solution from its components is found to be 40.96 cc. per atom of sodium. With decreasing concentration, the value of ΔV increases, reaching a maximum of 43.37 cc. per atom of sodium at a concentration of 11.25 moles of ammonia per atom of sodium. Beyond this concentration, the value of ΔV diminishes slowly. Judging by the form of Curve 2 (Fig. 3), as well as by that of the ΔV curve (Fig. 4), it is probable that, with decreasing concentrations, the value of ΔV approaches a constant value somewhat less than 40 cc. per atom of sodium. The

Fig. 4.

most dilute solution measured contained 32.6 moles of ammonia per atom of sodium with a density of 0.6582, which corresponds to a volume concentration of 1.138 *N*. At this concentration the solutions are rapidly approaching a constant condition as regards the state of the dissolved substance.

The volume change accompanying the formation of these solutions is a striking fact. It amounts to almost twice the original volume of the sodium. The heat effect accompanying the solution of sodium in liquid ammonia is inconsiderable. About 1500 calories are absorbed per atom of sodium and the value diminishes with increasing concentration.⁸ If we bear in mind the fact that, in these solutions, sodium is present as a

⁸ This value is based on measurements carried out by Mr. J. A. Ridderhof in this Laboratory. The detailed results will be published later.

normal sodium ion, we must ascribe the volume change chiefly to the electron which, freed from the constraints under which it exists in the solid metal, occupies a relatively large volume in the solution. In no other case heretofore investigated, either in processes of solution or of compound formation, has a volume change of this magnitude been observed. It is known that the electron in liquid ammonia solution at higher concentrations is free to move as it is in metals. Since we have no adequate conception of the state of the electron in metals, we are unable to draw any definite conclusions regarding its state in liquid ammonia. However, it may be safely concluded that the electron is not combined with the sodium ion and that at low concentrations, at any rate, the electron is associated with ammonia molecules.

The peculiar form of the ΔV curve at higher concentrations cannot be accounted for at this time. It is known that in concentrated solutions of the alkali metals in liquid ammonia, many properties exhibit singularities. The electrical conductance, for example, undergoes a tremendous increase in value with concentration as was shown by Kraus and Lucasse, while the temperature coefficient of the conductance exhibits a sharp maximum in the neighborhood of normal concentration.¹ The concentrations at which these singularities occur differ in the case of different properties.

Summary

The density of solutions of sodium in liquid ammonia has been determined at -33.8° at concentrations ranging from 32.6 moles per atom of sodium up to the saturation point.

The density of these solutions is lower than that of either constituent.

From the density values the increase in volume accompanying the solution of sodium in liquid ammonia has been calculated. The volume increase amounts to 40.96 cc. for a saturated solution and increases with increasing dilution to a maximum of 43.14 cc. for a solution containing 11.2 moles of ammonia per atom of sodium. On further dilution the value gradually diminishes and apparently approaches a limiting value in the neighborhood of 40 cc. At -33.8° the saturated solution of sodium in ammonia contains 5.48 moles of ammonia per atom of sodium.

DIPHENYLAMINE AS A QUALITATIVE REAGENT FOR ZINC

BY W. H. CONE AND L. C. CADY

RECEIVED JULY 5, 1927

PUBLISHED SEPTEMBER 2, 1927

The qualitative separation of zinc from chromium by the systems of analysis in general use requires considerable time. The production of the green cobalt zincate used as a confirmatory test is dependent upon the comparative amounts of cobalt nitrate and zinc present. Properly adjusting these amounts offers considerable difficulty to inexperienced analysts. The employment of diphenylamine and diphenylbenzidine as indicators in the titration of zinc¹ suggested their utilization in a qualitative test for zinc. A 0.5% solution of potassium ferricyanide and one gram of diphenylamine dissolved in 100 cc. of glacial acetic acid are the solutions used in this test.

Method

After the separation of the iron and aluminum groups by sodium hydroxide and sodium peroxide, the filtrate containing the aluminum group is acidified with hydrochloric acid, ammonium chloride is added, and the aluminum precipitated with ammonium hydroxide. The filtrate containing the chromium and zinc is acidified with acetic acid and divided into two equal parts. One part is tested for chromium and the other for zinc. To the part to be tested for zinc, five drops of the diphenylamine acetate solution and 5 cc. of the 0.5% potassium ferricyanide solution are added. The immediate appearance of a dark brown, green or purplish-black turbidity indicates the presence of zinc.

To test for any zinc that might be carried over into the iron group, the sulfides of zinc, cobalt and nickel are stirred for a few minutes with cold, dilute hydrochloric acid and filtered. The hydrochloric acid solution is boiled until all of the hydrogen sulfide is expelled, sodium hydroxide is added to alkalinity, the solution cooled and one gram of sodium peroxide added in small portions, with stirring. The mixture is boiled to decompose the excess sodium peroxide, cooled and filtered. The filtrate containing the zinc is acidified with acetic acid and the diphenylamine acetate and potassium ferricyanide are added as above.

Knop² states that in the absence of iron salts no coloration is produced by bichromate in a dilute solution of diphenylamine sulfate. This was found to be true only when the amount of bichromate present was small, less than .05 mg. per cc., a blue color being produced immediately if the concentration of bichromate was .05 mg. per cc. or greater. By using diphenylamine acetate instead of diphenylamine sulfate no color

¹ Cone and Cady, *THIS JOURNAL*, 49, 356 (1927).

² Knop, *ibid.*, 46, 263 (1924).

was produced unless the amount of chromium present was over 10 mg. of potassium bichromate per cc. of solution. This makes it possible to test for zinc in the presence of bichromate.

The color produced is dependent upon the relative amounts of zinc and chromium present. If much chromium is present the color will vary from a brown to a brownish-black. If chromium is absent the color will vary from a green to a purplish-black, depending on the amount of zinc present. The presence of chromium may cause the solution to turn dark on long standing even in the absence of zinc.

The following table shows the colors produced by varying the amounts of zinc and bichromate. Five cc. of potassium ferricyanide solution and five drops of diphenylamine acetate solution were used in each test.

TABLE I
COLORS PRODUCED BY VARYING MIXTURES OF ZINC AND BICHROMATE IONS

Mg. Zn per cc.	Mg. $K_2Cr_2O_7$ per cc.	Color produced
0.02	None	Pale green
.02	0.5	Greenish-yellow
.02	5.0	Brownish turbidity
.04	None	Greenish-black
.04	0.5	Greenish-brown
.04	5.0	Brown
.2	None	Blue violet
.2	0.5	Black
.2	5.0	Black

All the colors in the above table were quite distinct except when 0.02 mg. of zinc and 5.0 mg. of potassium bichromate were used, but even then there was a marked turbidity as compared with a potassium bichromate solution treated in the same manner.

A small amount of zinc ferrocyanide is always precipitated, due to the reduction of some ferricyanide to ferrocyanide by the diphenylamine. However, under the conditions prevailing any such zinc ferrocyanide formed is always dark colored on settling. Diphenylamine was used in preference to diphenylbenzidine as it is much cheaper and gives equally good results.

Summary

1. The use of diphenylamine as a qualitative reagent for zinc shortens the time required for the analysis of the aluminum and iron groups.
2. The test is more delicate than the cobalt zincate test.
3. The amount of zinc present may be estimated by the depth of the color produced.

THE COEFFICIENT OF SAPONIFICATION OF ETHYL ACETATE BY SODIUM HYDROXIDE

BY ETHEL M. TERRY¹ AND JULIUS STIEGLITZ²

RECEIVED JULY 5, 1927

PUBLISHED SEPTEMBER 2, 1927

An accurate determination of the coefficient of saponification of ethyl acetate by sodium hydroxide in mixtures of about one-hundredth molar concentration was undertaken as a part of the studies of catalysis carried out in this Laboratory under the direction of one of us.

The general method of work was not new. However, each detail of operation was carried out with greater precision than had been attempted before. Accurately measured volumes of reaction mixture were discharged at noted times into measured quantities of acid, calculated to be slightly in excess of that needed to neutralize the sodium hydroxide in the samples taken. The excess acid was then titrated and the concentration of sodium hydroxide calculated from the data thus obtained. The critical points in the success of the work were, first, the establishment of a suitable technique for handling the solutions without contamination with carbon dioxide of the air, and, second, the design of an apparatus which permitted very rapid discharge of accurately measured volumes of reaction mixture without exposure of the main solution to air. Details of the method and the preparation of materials will be found in Part II of this paper.

¹ The work herewith presented was completed in 1913 and embodied in the dissertation of one of us in partial fulfilment of the requirements for the degree of Doctor of Philosophy at the University of Chicago.

² The present investigation was designed to lay the foundation for a critical study by exact methods of catalysis by alkalies as affected by ionization, by the presence of salts and by other factors. The further development of the study was carried out under the direction of Dr. Terry, acting at first as my research assistant but later acting independently. The results of these later investigations will be published by Dr. Terry and her collaborators as follows:

Influence of Added Salts on the Velocity of Saponification of Ethyl Acetate by Sodium Hydroxide. I, by S. D. Wilson (1916); II, by Ralph E. Nelson (1918).

The Coefficient of Saponification of Methyl Acetate by Sodium Hydroxide, by W. T. Gooch (1918).

Influence of Light on the Saponification of Ethyl and Methyl Acetate by Sodium Hydroxide, by W. T. Gooch (1918).

The Saponification of Ethyl Formate by Ammonium Hydroxide in the Presence of Ammonium Salts, by E. N. Roberts.

The delay in publication has been altogether due to pressure of work on the present writer. Dr. Terry kindly consented finally to undertake the critical study of the results as a whole in the light of more recent knowledge of the nature of solutions and has developed a theory covering the data obtained under a wide range of experimental conditions.

This theory will be presented by Dr. Terry in another paper.—Julius Stieglitz.

The coefficient of the reaction was calculated by the well-known bi-molecular reaction equation, $dx/dt = K(A - X)(E - X)$. K is the coefficient; A represents the initial concentration (moles per liter of solution) of sodium hydroxide; E , the initial concentration of ester; X is the concentration or moles per liter of solution of alkali or ester used in the reaction at the moment considered; t is the time in minutes. The integrated form for the interval between two observed times, t_1 and t_2 , is

$$K = \frac{2.303}{(A - E)(t_2 - t_1)} \log \frac{(E - X_1)(A - X_2)}{(A - X_1)(E - X_2)}$$

13	.009984	.008106	..	6.780
14	.009984	.008055	..	6.790
15	.009986	.008112	..	6.820
17	.009986	.008165	..	6.790

Average 6.79

Change in reaction coefficient for rise of $0.20^\circ = 0.09$.

Therefore, coefficient for $25.00^\circ = 6.75$.

The average temperature (approximately 25°) per minute during the measurement of the reaction was computed and called the temperature of reaction. Then measurements were made at two-tenths of a degree higher temperature and the coefficient determined. From this it was estimated that the coefficient increased by 0.0045 for a rise of 0.01°. The results of each experiment were then corrected for difference in temperature from 24.91 in the first series or 25.11 in the second series. Data from a typical experiment are given in Table I. A summary of experiments appears in Table II.

When further studies were made on the saponification of ethyl acetate, these measurements were repeated from time to time as a means of ascertaining that experimental conditions were being kept constant. A summary of the data of various workers is given in Table III, together with a statement of the number of experiments represented, and the average and the maximum deviation of values from the average for the coefficient at 25.00° by each worker.

TABLE III

SUMMARY OF VALUES FOUND BY DIFFERENT WORKERS IN THIS LABORATORY (REF. 1)

Observer	No. of expts.	Av. coeff.	Av. dev. from mean, %	Max. dev., %
Terry (1913)	17	6.75	0.06	0.4
Wilson (1916)	8	6.76	.04	.3
Gooch (1918)	8	6.77	.2	.6

From Table III it will be seen that the results were reproducible to within one-third of one per cent. However, the error in the evaluation of the coefficient was three-quarters of one per cent. because of limitations of accuracy of measurement of time and of volume of solutions as will be explained in Part II.

TABLE IV

SUMMARY OF OLDER WORK

Experimenter	NaOH	Ethyl acetate	Temp.	Coeff., K	Coeff., at 25°
Warder ³	0.02	0.02	25	6.4	6.4
Ostwald ⁴	.025	.025	25	6.48	6.48
Arrhenius ⁵	.025	.025	24.7	6.59	6.77
	.0125	.0125	24.7	6.48	6.66
	.00625	.00625	24.7	6.58	6.77
Cohen ⁶	.025	.025	25	6.86	6.86
Reicher ⁷	0.02-03	.016-024	24.22	6.15	6.36
Crichton ⁸	.01	.01	24.85	6.47	6.84

³ Warder, *Ber.*, 14, 1361-65 (1881). Coefficient at 25° is calculated from his temperature coefficient.

⁴ Ostwald, *J. prakt. Chem.*, 35, 112 (1887); also Ref. 5, note 4.

⁵ Arrhenius, *Z. physik. Chem.*, 1, 110 (1887).

⁶ Cohen, *Proc. Acad. Sci. Amsterdam*, 2, 618 (1900).

⁷ Reicher, *Ann.*, 228, 257 (1885).

⁸ Crichton, *Proc. Roy. Soc. (London)*, 78, 157 (1907).

The value 6.76 may, therefore, be taken for the coefficient at 25° with the certainty that the error is less than three-fourths of one per cent.

The necessity of the above work will become apparent from Table IV, which contains a summary of the results of previous workers. Except where otherwise indicated, the temperature coefficient of 0.0045 for 0.01° change was used in estimating the reaction coefficient at 25°. A divergence of 7.5 per cent. will be observed between the highest and lowest results.

Part II. Experimental Detail

All vessels were filled with carbon dioxide-free air before they were used. When a transfer of solution was made, the opening of the flask which received the liquid was plugged lightly with cotton in the free space between buret tip or discharge tip and neck, etc. Only pure (carbon dioxide-free) air was allowed to enter the vessel from which the discharge was made.

Solutions were made with water of not greater than 1×10^{-6} mho conductance. All solutions, whether acid or alkaline, were handled as described above.

Sodium hydroxide was made by plunging freshly cut pieces of sodium under water at 0°. Each piece was held in a copper gauze basket, which was withdrawn as soon as the reaction was over. An atmosphere of carbon dioxide-free nitrogen was maintained over the water during the operation. Tests showed that no contamination of the solution by the copper basket took place.

Hydrochloric acid used in the titrations was standardized by the silver chloride method.

Ethyl acetate was made in four different ways: action of (1) acetyl chloride on alcohol; (2) acetic acid on alcohol, catalyzed by hydrochloric acid; (3) acetic anhydride on alcohol; and (4) alcohol, sulfuric acid and acetic acid, as described by Wade and Merriman.⁹ In each case the final purity of the product was tested by saponifying a weighed sample of ester and titrating the unused alkali. A fifth sample was obtained from Kahlbaum and purified by fractional distillation.

The indicator used in the titrations was phenolphthalein. It was purified by the method of McCoy¹⁰ and dissolved in carbon dioxide-free alcohol.

The end-point of the alkalimetric titrations was taken as the first faint color of the indicator. This is reported to represent a hydrogen-ion concentration close to 10^{-8} .¹¹ The accurate observation of this color required white light and a true white background. A so-called daylight lamp was found to be a great help in securing the correct conditions.

¹⁰ McCoy, *Am. Chem. J.*, 31, 507 (1904).

¹¹ Clark, "The Determination of the Concentration of Hydrogen Ion," Williams and Wilkins, Baltimore, 1922, p. 301.

Air for filling containers for samples to be titrated was purified by filtration through moist soda lime about one meter in length. That used for the larger containers was stored over molar sodium hydroxide usually about 24 hours prior to use. Test of the purity of the air was made by titrating 50 cc. of water which had been shaken with a 500cc. sample of the air. One drop of 0.01 *N* baryta was sufficient to bring the color change of the indicator, phenolphthalein, if the air was of acceptable purity.

Apparatus.—The apparatus was simply an improvement of Reicher's device.⁷ It can best be described by reference to Fig. 1. A is a container for the reaction mixture.

B is a removable head. It consists of a rubber stopper, backed with a monel metal plate fitted with lugs which permitted rapid clamping into place. Through the stopper passed a Beckmann thermometer, an air outlet tube with the stopcock 1 and the discharge tube C. A mercury pipet D was connected to A through stopcock 2. Mercury was fed into the pipet through the stopcock 3 from a reservoir under pressure from water from the hydrant. The flow of mercury to A from D was controlled by stopcock 3. The mercury pipet had two graduated scales at *n* and *m*, as indicated, and the volumes between the various graduations were known. At the start of the experiment the connections from C to A were filled with mercury as shown. All rubber-to-glass or glass-to-metal joints were made with de Khotinsky cement.

The apparatus was contained in a de Khotinsky thermostat, regulated with a constancy of 0.01°. The thermometers used were standardized by comparison with two Baudin thermometers.

Manipulation of Apparatus.—When a mixture of sodium hydroxide and ethyl acetate solution had been made in A, the top was clamped into place and mercury was forced into A to displace the air. The operator closed the discharge tube with the left hand and finally closed the air tube after the exclusion of air had been completed. A container holding the necessary acid was then put in place before the tube C and mercury discharged from the pipet into A, thus displacing a sample of the same volume from A into the receiver. The discharge occupied about five seconds and it was usually possible to collect the first sample two minutes after the original mixture had been made. The volume of the discharge, about 100 cc., was known from the levels of the mercury in *m* at the start and in *n* at the end of the discharge. The time of half discharge was observed and also the temperature of the mixture.

Fig. 1.

Analysis of Samples.—As has been stated, samples were discharged into a known quantity of acid. Before titrating the excess acid the mixture was frozen and allowed to thaw during the titration at such a rate that the last of the ice melted just before the titration was completed. From the data of titration, the concentration of sodium hydroxide at the time of discharge was calculated. The alkali was always greater in concentration than the ester. Hence, the final concentration of alkali gave the difference in concentration of alkali and ester, and thus the calculation of the concentration of ester at the time of each discharge was made possible.

Accuracy of Results.—Rigid adherence to an established technique permitted the reproduction of results to within one-third of one per cent. There were, however, certain limitations of the absolute accuracy of the results. When carbon dioxide is rigorously excluded from titrations of 0.01 *N* sodium hydroxide solutions, they may be completed with an accuracy limited only by the correct choice of indicator and the reading error of the buret. If allowance is made for the error in measurement in volumes not only of samples of reaction mixture, but also of the acid used to neutralize the sample and of the alkali used in completing the titration, then an error of 0.10 cc. will be seen to be the maximum probable. If the measurements had not been carried out with a strict observance of the conditions of calibration of the apparatus used, so great an accuracy could not be claimed. An error of 0.10 cc. was of no importance in the measurements made during the progress of the reaction. However, at the end of the reaction the titration results were equivalent to only 20–30 cc. of reagent, so that this error could then cause an error of one-half of one per cent. in the evaluation of $(A - E)$ and, therefore, of the coefficient.

Another source of error was the determination of the time of half discharge. This was observed by cooperation of two persons, one watching the descent of the mercury and the other watching the stopwatch in the usual way. The error could not have been greater than two-fifths of a second and the net effect on the accuracy of the determination of the coefficient was not over one-fourth of one per cent. Since the accuracy of the stopwatch was checked by comparison with a standard timepiece with which it agreed within five seconds over a period of 24 hours, no other error was introduced.

Therefore, the absolute accuracy of the value of the coefficient of the saponification may be taken to be better than three-fourths of one per cent.

Summary

Measurements were made of the velocity of saponification of ethyl acetate by sodium hydroxide in aqueous solution in mixtures of approximately one-hundredth normal concentration. The coefficient of the reaction calculated on the basis of the bimolecular equation is 6.76 for 25.00° and is accurate to three-fourths of one per cent. A change of 0.10° in temperature alters the coefficient by 0.045. The technique established

has been the basis of forthcoming studies on different aspects of the problem of catalysis of ester saponification in water solution.

CELLS OF THE STANDARD CELL TYPE WITH LOW ELECTROMOTIVE FORCES

By WARREN C. VOEBURGH

RECEIVED JULY 15, 1927

PUBLISHED SEPTEMBER 2, 1927

A standard cell with a low electromotive force would have some advantages over the ordinary standard cell in the measurement of small electromotive forces. Obata¹ has investigated the possibility of using for this purpose the cells

Taylor and Perrott² set up and measured some cells similar to Cells 1 and 2, the only difference being that they used an unsaturated lead amalgam, 0.72% lead. By combining the electromotive forces of their cells with the electromotive force of the cell

which was measured by Brönsted,³ and that of the cell

which was measured by Gerke⁴ the electromotive forces of Cells 1 and 2 can be calculated. For Cell 1 at 25° the value 0.1432 volt is obtained from the results of Taylor and Perrott, while Obata found 0.1408 volt. Similarly for Cell 2 at 25° the value 0.1020 volt is obtained from the results of Taylor and Perrott, while Obata found 0.0996 volt. Thus, there is a difference of about 2.2 mv. between the results of Taylor and Perrott and those of Obata for both cells.

Van Ginneken and Kruyt⁵ have given as the requirement for a standard cell that, with temperature and pressure constant, both electrode systems must be invariant systems of the same components. The cells of Taylor and Perrott did not conform to this specification because the lead amalgam was not a two phase amalgam. One electrode system, therefore, was not an invariant system. Also, the other electrode system contained no lead. The cells of Obata were not true standard cells because the cadmium-amalgam electrode system contained no lead.

To make Cells 1 and 2 into true standard cells, according to the specification of Van Ginneken and Kruyt, the cadmium amalgam must be replaced by an amalgam saturated with both cadmium and lead. The system cadmium-lead-mercury has been studied by Kremann, Prammer and Helly,⁶ who found that within a certain range of compositions the cadmium activity was constant. The author⁷ has tried replacing the cadmium amalgam of the Weston standard cell with a cadmium-lead amalgam having a composition within the constant cadmium activity range. The cells were as reproducible as true Weston cells and had an electromotive force 1.13 mv. higher at 25°.

The work described below was undertaken to study the effect of replacing the cadmium amalgam of Cells 1 and 2 with cadmium-lead amalgam.

Preparation of Materials

Two lots of lead amalgam were prepared, both containing 10% of lead. The first was prepared by electrolysis of a saturated lead chloride solution with a mercury cathode and a platinum anode. The lead chloride was prepared by adding redistilled hydrochloric acid solution to a solution of twice-recrystallized lead nitrate. The mercury was passed through a column of mercurous nitrate solution and redistilled at low pressure in a current of air.

The second lead amalgam was prepared by dissolving the required amount of lead in some of the above-described mercury. The lead was prepared by the method of Richards and Wadsworth⁸ from the twice-recrystallized nitrate.

The cadmium-lead amalgam was prepared by depositing cadmium by electrolysis in some of the first lead amalgam. By adding small amounts of the above-described mercury and lead, the composition was adjusted to 11% lead, 9% cadmium and 80% mercury, or 10, 15, and 75 atomic per cent., respectively. This composition is within the range in which the cadmium activity is constant.

The cadmium chloride and the cadmium iodide were both recrystallized twice.

The lead chloride and the lead iodide were prepared by precipitation from a solution of the twice-recrystallized nitrate, the first with redistilled hydrochloric acid solution and the second with a solution of recrystallized potassium iodide. Both were recrystallized.

Preparation of the Cells

The cells were set up in glass H-vessels of the type used for Weston cells.⁹ The amalgams were melted by heating, and cadmium-lead amalgam was placed in one leg of the vessel and lead amalgam was placed in the other. For the chloride cells some lead chloride was ground in a mortar with some cadmium chloride and was made into a paste with cadmium chloride solution. The paste was placed on top of the lead amalgam to a depth of at least 1 cm. Cadmium chloride crystals ground with some of the saturated solution were placed above the paste and also above the cadmium-lead amalgam. More crystals were then added, and the cells were filled to a point above the cross-arm with saturated cadmium chloride solution. The iodide cells were set up similarly. The

⁹ Vosburgh and Eppley, *ibid.*, **45**, 2269 (1923).

cells were usually evacuated to remove air bubbles, and the tops were flushed out with nitrogen and then sealed.

In the preparation of the first group of chloride cells, Cells 407-409, and the first group of iodide cells, Cells 340-342, the precautions previously described¹⁰ for the exclusion of oxygen in the preparation of Weston cells were taken. In the others no attempt was made to protect the materials from the air while the cells were being set up. In the case of the chloride cells this omission seemed to make no difference in the electromotive force, but it might have been the cause of the 0.2 mv. difference between the two groups of iodide cells.

In the first group of chloride cells the electrolyte contained a small amount of hydrochloric acid. The solution was made by saturating a 0.001 *M* hydrochloric acid solution with cadmium chloride. In the other cells the electrolyte was a saturated solution of cadmium chloride, or cadmium iodide, in redistilled water.

The first lead amalgam was used in all except Cells 456-459, in which the second lead amalgam was used.

Electromotive-Force Measurements

The electromotive forces were measured by means of a Leeds and Northrup thermocouple potentiometer. The potentiometer was accurate to 0.02% according to the data of the manufacturer. It was not checked. The standards were the Weston cells used as standards in previous investigations.¹¹ They were probably accurate to 0.01%. The standards were maintained in an oil thermostat at $25 \pm 0.02^\circ$ throughout the investigation. The experimental cells were kept in an oil thermostat capable of being maintained within 0.01° of the desired temperature. They were always maintained at constant temperature for a period of at least three days before important measurements. Tables I and II give the electromotive forces at 25° over a period of 8 and 9 months, respectively.

TABLE I

Cells	Cd(Pb, Hg) CdCl ₂ .2.5H ₂ O, SAT. CdCl ₂ .2.5H ₂ O + PbCl ₂ , SAT. Pb(Hg)				
	Electromotive force, 25°				
	1 month v.	2 v.	4 v.	6 v.	8 v.
407-409	0.13866	0.13869	0.13871	...	0.13807
429-430	.13870	.1386913822
456-45913873	0.13870	0.13865	...

TABLE II

Cells	Cd(Pb, Hg) CdI ₂ , SAT. CdI ₂ + PbI ₂ , SAT. Pb(Hg)				
	Electromotive force, 25°				
	1 month v.	3 v.	5 v.	7 v.	9 v.
340-342	0.10082	...	0.10088	0.10088	0.10082
427-428	.10065	0.1006510056	...

The chloride cells were quite reproducible. The average variation of the nine cells from the mean was about ± 0.03 mv., and the maximum variation was 0.13 mv. They were quite constant for a period of 4 to 6 months at least. The first two groups decreased somewhat in electromotive force after a change in temperature to 40° and back to 25° , as indicated by the values in the column of Table I headed 8 months. They

¹⁰ Vosburgh, *THIS JOURNAL*, 47, 1258 (1925).

¹¹ See Ref. 10, p. 1256.

became variable after this and one showed definite signs of deterioration.

The iodide cells were not as reproducible as the chloride cells. They did not give evidence of permanent change in electromotive force during the time they were under observation. The average variation from the mean of the 5 cells, when they were 1 month old, was ± 0.08 mv., and the maximum variation was 0.3 mv. The two groups differed by about 0.2 mv.

After constancy was assured at 25° , the temperature of the thermostat was changed successively to 20, 15, 20, 25, 30, 35, 40, 35, 30 and 25° , the cells being maintained at each temperature for 3 days to 2 weeks. The temperatures were measured by means of two platinum resistance thermometers and a mercury thermometer which had been checked by the Bureau of Standards. Temperatures were probably accurately measured to $\pm 0.01^\circ$.¹² Several electromotive-force measurements were made at each temperature. The chloride cells showed little hysteresis. After a temperature change, particularly after a decrease, the electromotive force usually changed a few hundredths of a millivolt over a period of 3 or 4 days. The iodide cells showed much more hysteresis. After an increase in temperature the electromotive force became too high. It decreased very slowly and never came to equilibrium in the time allowed before the next temperature change. With a decrease in temperature the effect was the opposite. The hysteresis was more pronounced in Cells 340-342 than in Cells 427-428.

The results of the measurements at different temperatures are given in Table III. Each value is the average of two measurements, one after an increase in temperature and the other after a decrease, except the values at 25° , 15° and 40° . At 25° the equilibrium value before the temperature was changed is given, and at 15° and 40° there was only one measurement at each temperature.

TABLE III
ELECTROMOTIVE FORCES AT DIFFERENT TEMPERATURES

Cells	Electromotive force					
	15° v.	20° v.	25° v.	30° v.	35° v.	40° v.
407-409	0.14030	0.13955	0.13872	0.13914	0.13997	0.14082
429-430	.14030	.13953	.13871	.13913	.13998	.14082
340-34209934	.10082	.10195	.10329	...
427-428	.09800	.09934	.10064	.10192	.10323	.10456

In the case of the iodide cells there was always a difference between the two values at the same temperature because of the hysteresis. In the case of Cells 340-342 this usually amounted to 0.3 mv. to 0.4 mv., but it was less than 0.1 mv. for Cells 427-428. It was obvious that neither of the two values represented the equilibrium condition, but it was assumed that the mean of the two would be approximately the equi-

¹² See Vosburgh, *J. Optical Soc. Am.*, 12, 513 (1926).

librium value. Calculated in this way the results for the two of iodide cells agreed very well.

Discussion

The Chloride Cell.—If the electromotive force of the cell

be plotted against temperature, the graph shown in Fig. 1 is obtained. The graph consists of two branches, one of which is a straight line, and the other, the one on the left, is nearly so. The two branches meet at about 26.2°. Below 26.2° the cell has a negative temperature coefficient,

Fig. 1.—Relation between the electromotive force of the cell $\text{Cd(Pb, Hg)} \mid \text{CdCl}_2 \cdot 2.5\text{H}_2\text{O, sat.} \mid \text{CdCl}_2 \cdot 2.5\text{H}_2\text{O} + \text{PbCl}_2, \text{ sat.} \mid \text{Pb(Hg)}$ and the temperature.

and above 26.2° it has a positive one. This is an indication of a transition point of some substance in the cell. According to Dietz¹³ and Cohen and Bruins¹⁴ the substance $\text{CdCl}_2 \cdot 2.5\text{H}_2\text{O}$ is stable between -5 and 34° . Above 34° the monohydrate is the stable form. Fig. 1 gives no evidence of this transition point, the curve being a straight line between 26.2 and 40° .

Evidently as the temperature was raised from 25 to 30° transition took place. After the temperature had decreased from 30 to 25° , the

¹³ Dietz, *Z. anorg. Chem.*, 20, 257 (1899).

¹⁴ Cohen and Bruins, *Verslag Akad. Wetenschappen Amsterdam*, 25, 739 (1917).

last change in the series of measurements, the electromotive force at the latter temperature did not agree with the former values at 25°, but was abnormally low. It fell on the straight line representing the temperature-electromotive force relation above 26.2°, indicating that transition had not taken place when the temperature decreased from 30 to 25°. The electromotive force remained low for a considerable period and was somewhat erratic for several months after the temperature change. No abnormal behavior was noticed after any of the other temperature changes.

Between 15 and 26.4° the electromotive force of the chloride cell is given by the equation

$$E = 0.13872 - 0.000168 (t - 25) - 0.0000010 (t - 25)^2$$

This can be combined with the equation for the electromotive force of the cell

namely,

$$E = 0.00113 + 0.000025 (t - 25) + 0.0000002 (t - 25)^2$$

giving for Cell 1

$$E = 0.13759 - 0.000193 (t - 25) - 0.0000012 (t - 25)^2$$

Obata found a value 3 mv. higher at 25°, while a value 5.6 mv. higher can be calculated from the results of Taylor and Perrott.

If the electromotive force of Cell 1 is combined with the electromotive force of Cell 4 and that of the cell¹⁶

the electromotive force of the cell

is found to be

$$E = 0.1824 - 0.000453 (t - 25) - 0.0000012 (t - 25)^2$$

Therefore, for the reaction

$\Delta F_{25} = -8417$ cal., $\Delta S_{25} = -20.9$ and $\Delta H_{25} = -14,650$ cal.

Thermochemical data determined at temperatures of 18 to 20° are available for the calculation of the heat of reaction of this cell. Thomsen found $\Delta H_{18} = -93,240$ cal. for the heat of formation of cadmium chloride, and Braune and Koref¹⁷ found $\Delta H_{20} = -85,700$ cal. for the heat of formation of lead chloride. Cohen and Bruins¹⁸ found $\Delta H_{18} = -7110$ cal. for the heat change accompanying the formation of the hydrate of cadmium chloride in the saturated solution. Combining the thermochemical data, $\Delta H_{18} = -14,650$ cal., while from the data for Cell 8, $\Delta H_{18} = -14,420$ cal.

¹⁵ Ref. 7, p. 2534.

¹⁶ Gerke, *Chem. Reviews*, 1, 377 (1925).

¹⁷ Braune and Koref, *Z. anorg. Chem.*, 87, 183 (1914).

¹⁸ Cohen and Bruins, *Verslag Akad. Wetenschappen Amsterdam*, 26, 587 (1917).

The chloride cell would not make a good standard cell. Its temperature coefficient is large, and on account of the peculiar nature of the temperature-electromotive force relation, the discovery of another cell which could be combined with it to eliminate the temperature coefficient over a sufficient range of temperature is improbable. The formation of a metastable state after a decrease in temperature from 30 to 25° is a serious disadvantage. One of the cells failed toward the end of the temperature coefficient determination, and the others were in a metastable state and erratic after this determination was completed, making the constancy of the cells over long periods of time questionable.

The Iodide Cell.—The cell

has a practically linear temperature-electromotive force relation between 15 and 40°. It does not show any irregularity such as the chloride cell does. The temperature formula is not of the highest degree of accuracy on account of the hysteresis. The following should give the electromotive force within ± 0.1 mv.,

$$E = 0.1007 + 0.00026 (t - 25)$$

If the electromotive forces of Cells 6 and 9 are combined, the electromotive force of Cell 2 is found to be

$$E = 0.0996 + 0.000235 (t - 25) - 0.0000002 (t - 25)^2$$

This agrees within 0.1 mv. with the value found by Obata.

If the electromotive forces of Cells 2, 7 and 4 are combined, the electromotive force of the cell

is found to be

$$E = 0.1444 - 0.000025 (t - 25) + 0.0000002 (t - 25)^2$$

Therefore, for the reaction $\text{Cd} + \text{PbI}_2 \longrightarrow \text{CdI}_2 + \text{Pb}$, $\Delta F_{25} = -6664$ cal., $\Delta S_{25} = -1.15$ and $\Delta H_{25} = -7008$ cal.

The heat of reaction can be calculated from thermochemical data. Braune and Koref¹⁹ found $\Delta H_{20} = -41,850$ cal. for the heat of formation of lead iodide. Gerke²⁰ found a value in close agreement with this electrochemically. For the heat of formation of cadmium iodide, Thomsen found $\Delta H = -48,830$, while Taylor and Perrott²¹ found $\Delta H = -48,440$. The heat of reaction for Cell 10 on the basis of Thomsen's heat of formation is $\Delta H = -6980$ cal., and on the basis of Taylor and Perrott's heat of formation is $\Delta H = -6590$ cal. The agreement of the former with the value $\Delta H_{20} = -7034$ cal. calculated from the electromotive force and temperature coefficient of Cell 10 is very good.

²⁰ Gerke, Ref. 4, p. 1703.

²¹ Ref. 2, p. 492.

The large and persistent hysteresis of Cell 10 and its large temperature coefficient are disadvantages to its use as a standard cell.

Other Cells.—A few cells were set up similar to Cells 5 and 9 but with bromide or sulfate electrolytes. Neither the cells with the bromide electrolyte nor those with the sulfate electrolyte were reproducible, and both groups of cells were variable. It is to be noted that Mellon and Henderson²² found that lead standard cells which contained a lead-amalgam-lead-sulfate electrode, were not constant when the electrolyte was a cadmium sulfate solution and were not as reproducible as the cells in which some other salts were used as the electrolyte.

Summary

The cells

were set up and their electromotive forces were measured over a period of several months at 25°, and also at 5° intervals from 15 to 40°.

The electromotive force of the first cell was not in agreement with the values of similar cells measured by Obata and by Taylor and Perrott. The electromotive force of the second cell agreed well with that of a similar cell measured by Obata.

The temperature-electromotive force relation of the cell with the chloride electrolyte indicated a transition point at a temperature between 26 and 27°.

Neither of these cells seems to be especially well adapted for use as a low-voltage standard cell, the chloride cell having a transition point which would interfere, while the iodide cell shows marked and persistent hysteresis. Both have large temperature coefficients.

The heats of reaction were calculated and compared with the heats of reaction calculated from thermochemical data.

AN EXPERIMENTAL TEST OF THE GIBBS ADSORPTION THEOREM: A STUDY OF THE STRUCTURE OF THE SURFACE OF ORDINARY SOLUTIONS¹

BY JAMES W. MCBAIN AND GEORGE P. DAVIES

RECEIVED AUGUST 2, 1927

PUBLISHED SEPTEMBER 2, 1927

The object of this communication is to present a definite conception of the structure of the surface of ordinary solutions as deduced from several different kinds of evidence and confirmed rather directly by absolute measurements of adsorption in and near the surface of solutions.

A clear picture of the structure of films of insoluble materials resting upon a solvent such as water has been gained through Rayleigh, Hardy and Adam in England, Devaux and Bancelin in France and Langmuir and Harkins in America. For example, a film of the insoluble palmitic acid on water is a coherent monomolecular film, all the molecules being oriented perpendicular to the surface. Far less has been known about soluble materials and about the two fundamental questions as to whether in such cases monomolecular films are formed and as to how far beneath the surface the influence of surface forces such as adsorption and orientation extends.

Some of the conceptions resulting from the adsorption of a soluble substance in the surface of a solution are illustrated in Fig. 1. Langmuir, in 1917, suggested that the adsorbed layer of dissolved substance might well appear as a monomolecular layer upon the surface (Fig. 1a). The data which he obtained from calculation in the absence of any direct measurements corresponded, however, to a curiously incomplete, although constant, monomolecular layer (Fig. 1b). To explain this discrepancy Donnan, in 1923,² suggested that the molecules were partially submerged and, therefore, separated in the surface (Fig. 1c), whereas Langmuir suggested hydration of each molecule or alternatively that in some cases such as phenol and aniline the molecules lie flat instead of standing in their usual orientation.

The present communication affords for the first time accurate measurements of the absolute amount of adsorption and in each case the amount actually adsorbed is definitely greater than that which could be packed on the surface as a monomolecular film. Hence we suggest that there is probably a fairly complete monomolecular film upon the surface, but that in addition to this there is an excess concentration, or adsorption, within the solution in the immediate neighborhood of the surface, ex-

¹ Read before the Mid-West Regional Meeting of the American Chemical Society at Madison, Wisconsin, May 28, 1926.

tending inwards for many molecular diameters (Fig. 1d). This is shown in Fig. 1d as consisting of chains of oriented molecules extending inwards from the surface into the solution.

Previous Evidence that a Surface Layer Has Depth.—

(1) The classical experiments of Hardy on lubrication have shown that a liquid between two metal surfaces can exhibit static friction even when the liquid layer is far deeper than the diameter of a molecule. This appears to be the first clear evidence that orientation of molecules may extend far below the actual surface. Of the two possible explanations of this undoubted effect, namely, either that the range of molecular attraction is great as compared with molecular diameter or, alternatively, that it is through a sort of chain effect that molecules are successively oriented through the depth of the liquid, of these we would prefer the second, although Hardy has favored the first.

(2) The studies of adhesion by McBain, Hopkins and Lee³ have shown that a thin film of adhesive between two surfaces may yield a joint several times as strong as the adhesive substance itself. Furthermore, the thinner the layer of adhesive the stronger the joint, and this influence becomes especially great when the films are excessively thin. These results we would likewise interpret in terms of the chain effect of orientation of molecules in the neighborhood of the surface.

(3) Other evidence is provided by the study of the viscosity of liquids

Fig. 1.—Diagrammatic representation of various conceptions of the structure of surfaces of ordinary solutions; (a) close-packed monomolecular layer of solute upon the surface, (b) curious incomplete monomolecular layer obtained by calculation using the simplified Gibbs' concentration adsorption formula, (c) Donnan's attempted explanation of (b) by assuming partial submergence, (d) the conception advanced in the present paper, a complete monomolecular film plus chains of oriented molecules of solute extending far below the surface.

Chem.*, 30, 114–25 (1926); (d) McBain and Lee, *Proc. Roy. Soc. (London)* 113A, 605–20 (1927); (e) *J. Soc. Chem. Ind.*, 46 (1926); (f) *Ind. Eng. Chem.*, 19, 1005 (1927).

in which solid particles are suspended. Hatschek⁴ has proved that even in the simplest of such systems the viscosity coefficient alters with the rate of shear, a phenomenon for which he has been at a loss to account. It cannot be due to solvation or aggregation of particles in such a system as starch granules suspended in the indifferent liquid, toluene; but it is in obvious agreement with the conception that a chain effect extends into the liquid from any solid surface which has oriented any of the superficial molecules. Tests should be carried out with polar liquids where this effect would be expected to be greatest; likewise with solutions such as aqueous *p*-toluidine.

(4) The most direct method of studying the structure of surfaces is by measurement of the absolute amount of adsorption in and near the surface. Euler⁵ has attempted absolute measurements of adsorption on gold and silver foils from solutions of silver nitrate, obtaining a result which is about double that for a monomolecular film of silver ions for this area of surface, assuming that the silver surface was smooth and continuous. This accords with our interpretation as illustrated in Fig. 1d, that is, a monomolecular layer in addition to the adsorption or excess concentration in the neighborhood of the solid surface. It should be borne in mind that adsorption in the surface of a liquid medium is very different from adsorption from a vapor or gas, because whereas in the liquid or solution the space below the surface is closely packed with contiguous molecules which merely have to be oriented, in the latter case the only molecules appreciably near the surface are those which are actually captured or adsorbed by the surface, and hence the surface effect cannot reach out from the actual surface into the gaseous space.

(5) In earlier experiments by W. C. M. Lewis⁶ to determine the adsorption of various materials at a liquid-liquid interface, in nearly every case the approximate adsorption as determined was mostly much larger than expected, often 100 times larger. However, many of these substances were colloidal and the results are ambiguous.

(6) The only determinations of the absolute adsorption of a substance from true solution at the air interface are those of Donnan and Barker,⁷ sixteen years ago, who employed an aqueous solution of nonylic acid. They blew a stream of air bubbles up through the solution which was placed in a simple still-head divided into a number of compartments

vertically above each other. They considered (erroneously, see below) that the partitions would prevent mixing of the liquids in the several compartments. They took for analysis the whole of the liquid except that in the uppermost compartment and, after mixing it until homogeneous, determined the loss of nonylic acid. They do not record any measurement of a corresponding gain in the uppermost compartment, neither was there any test of the effect of altering the age of the bubble or time of contact between air and solution. From the number and dimensions of the bubbles which had passed through the solution they knew the total area involved and they estimated the surface tension by means of drop numbers, using this also as their means of analysis. They compared their results with those computed from the surface-tension curve by means of the so-called Gibbs theorem: Γ , the excess of nonylic acid in the interface = $-\frac{c}{RT} \cdot \frac{d\sigma}{dc}$, where c is the concentration and σ the surface tension. Some uncertainty attached to the degree of dissociation in these extremely dilute solutions; in the results collected in Table I, four calculated values are given for comparison with Donnan and Barker's observations taken from Donnan and Barker's curve and Forch's curve for surface tension, respectively, calculated in each case for " i " alternately equal to 1 or equal to 2, that is, for no dissociation and for complete dissociation of nonylic acid.

TABLE I

THE OBSERVATIONS OF DONNAN AND BARKER ON THE ADSORPTION, Γ , OF NONYLIC ACID IN THE AIR-WATER INTERFACE COMPARED WITH THE VALUES PREDICTED FROM THE SO-CALLED GIBBS THEOREM

Concn. of soln., %	Γ obs., g. $\times 10^{-8}$	- Γ calcd. (g. $\times 10^{-8}$)—			
		Forch's curve " i " = 1	" i " = 2	Donnan's curve " i " = 1	" i " = 2
0.00243	9.5	5.8	2.9	5.5	2.6
.00500	15.2	12.3	6.1	11.4	5.7
.00759	10.9	15.8	7.9	12.6	6.3
.00806	9.15	16.3	8.1

* " i " is the degree of dissociation of nonylic acid in these solutions.

Since these four numbers constitute the only careful test of the adsorption in the air-water interface hitherto published, it is necessary to scrutinize them closely. They can be considered as confirming the order of magnitude of the effect but they are subject to serious error, as will be shown. Since they must be regarded as only semi-quantitative, no stress need be laid on the fact that they do not conform to Langmuir's prediction that they should reach a constant maximum value with increase of concentration; neither need attention be paid to the fact that the result of 10×10^{-8} g./sq. cm. gives an area of 26×10^{-16} sq. cm. per molecule, which is distinctly less than monomolecular and corresponds to the state of

affairs that is illustrated in Figs. 1b or 1c. Our reason for regarding the method as inherently erroneous is given in the following paragraph describing extensive series of careful determinations (about 100) carried out during several years in the Bristol Laboratory, and all discarded.

Rejection of All Results by the Donnan and Barker Method.—There is a close resemblance between the determination of transport numbers and a determination of adsorption by the stream of bubbles used in the Donnan and Barker method. In the first the transport is electrical, in the second the bodily movement is mechanical. In the first, a careful experiment requires a demonstration that the gain or loss in the anode compartment is equal to the loss or gain in the cathode compartment and that the middle portion is unchanged. In precision work it is customary to take a series of middle portions to avoid chance compensation. We had taken all these precautions, analyzing every portion separately by the accurate method of the Zeiss interferometer and testing the effects of concentration, time, total area, etc.

There is one fatal objection to all measurements by this method, that is, the pumping action that goes on throughout the apparatus every time a bubble is injected and passes through. Donnan and Barker were misled by a strange blank experiment in which they observed no mixing. Within each compartment the stream of bubbles necessarily causes rapid stirring, so that the liquid in each compartment is kept sensibly homogeneous. As each bubble is passed into the bottom of the apparatus its own volume of liquid is necessarily pumped into the next compartment above, and a similar volume of liquid is returned when the bubble leaves each of the compartments successively. Since there are perhaps 24,000 separate bubbles it is easy to compute the amount of mixing that is inevitable, given the size of bubble relative to a given compartment. Hence a stationary state is reached which is definitely illusory, giving much less than the true adsorption.

THE STOPPER METHOD.—We tried a method of circumventing the mixing between successive compartments by carefully arranging the diameter and rate of passage of the bubbles and the dimensions and form of the orifices between compartments so that no bubble should leave an orifice until the next bubble had just caught up to it and taken its place. With care a third bubble could be added so that two at a time acted as stoppers in each orifice. Great care is necessary to prevent the bubbles from actually touching the glass, through breakdown of the thin film of liquid between, and also the dimensions of orifices of the successive compartments have to be adjusted to the lessening hydrostatic pressure as the bubbles travel upwards. Hence this difficult technique was discarded in favor of the very easy experiments to be described later.

The Nature of the Findings of the Present Investigation.—The meas-

measurements to be described for solutions of *p*-toluidine, of camphor and of amyl alcohol give quantitative information as to the amount of adsorption per square centimeter of surface of their aqueous solutions. In the first place, the amount of adsorption which occurs is definitely much greater than the material which could be packed into a monomolecular layer according to the dimensions of molecules obtained from the study of insoluble films and from x-ray measurement of crystals. For example, there is one molecule of toluidine adsorbed for every 14×10^{-16} square centimeters of surface, whereas one molecule can cover 23×10^{-16} square centimeters of surface. One molecule of amyl alcohol is absorbed for each 9×10^{-16} square centimeters of surface, whereas it should cover 21×10^{-16} square centimeters. These and the similar results for camphor show that the measured adsorption is several times greater than the amount of material which can be accommodated in a monomolecular layer and we, therefore, deduce an arrangement such as that depicted in Fig. 1d, where adsorption occurs not only upon the surface but within it. This shows that surface forces and surface tension are conditioned not solely by the outermost layer of molecules but also by much deeper layers. The study of the surface tension of ordinary liquids by such investigators as Sugden⁸ has pointed to the similar conclusion that the total surface energy of a liquid is not defined entirely by the nature and orientation of the surface layer of molecules. Fig. 1d goes further in that it suggests a mechanism for this effect.

A second important result following from our numerical data is that the so-called Gibbs theorem, in which adsorption is related to concentration and surface tension, is shown to give highly erroneous values differing by several fold from those actually observed. Hence, this commonly used concentration formula must be rejected as being of only qualitative significance. In the following pages our method of experiment and its numerical results will be presented and afterwards it will be shown that a more careful consideration of the requirements of the true Gibbs formula, which involves thermodynamic quantities and all the components of the system (such as the gas used in bubbling) is required for adequate treatment on this subject.

Other Relations That Follow from the Conception of Chains of Oriented Molecules Extending Inwards from the Surface.—If this conception is correct it should find manifold applications and one should seek information in very diverse fields. For example, it affords an explanation of the otherwise surprising effect of inert fillers upon the strength and resiliency of rubber, as in rubber tires. It explains why extremely fine subdivision produces the greatest effect; the whole of the very extensive surface has the role of orienting the molecules in immediate contact with it and the

⁸ Sugden, *Trans. Faraday Soc.*, 22, 486 (1926).

chain effect extends with diminishing intensity into the surrounding rubber. Fine subdivision not only increases the surface but diminishes the distance between these orienting particles.

In a similar fashion inert fillers should increase the strength and elasticity of layers of adhesives, thus improving joint strength where the layers are not excessively thin (see Second Report of the Adhesives Research Committee, Appendix IV, 109-111 (1926)). Perhaps we have here the explanation of the effect of multiple gluing in increasing the strength of a joint, that is, the well-known great increase in strength of many joints when the adhesive is applied in successive thin coatings and each allowed to dry before the next is applied, and a final coat given just before the surfaces are brought together. Probably we fix successive chains before applying the next layer. All these suggestions should be accessible to direct experimental test.

Even the effect of oil upon troubled water, which Hardy has had to ascribe to the diminishing of its friction against the atmosphere may possibly be brought under this explanation, since the oil forms a stable film to which chains of stable molecules may be anchored. In other words, the conception assumes that a liquid is not always a liquid near its own surface but may become a semi-solid.

Even a pure liquid has been shown by H. B. Baker and others to consist of a mixture of simple and aggregated molecules and hence the composition and structure of the surface will be different from that of the bulk of the liquid. Several writers such as L. V. King and Ramden have shown that from physical and especially optical considerations, there is a tendency towards formation of minute protocrystalline aggregates of molecules throughout liquids, and this tendency must be greatly enhanced and given direction in the neighborhood of surfaces.

A New and Simple Method of Determining Absolute Adsorption in the Air-Water Interface

There are many possible ways of replacing the discarded Donnan and Barker method. The following is one of the simplest. It gives quantitative results accurate to a few per cent. and only a few hours are required for each determination. The principle is to use a long inclined tube of large diameter (1.6 meters long), so inclined that bubbles pass slowly along it, adsorbing to saturation value without appreciably altering the concentration of the liquid remaining in the tube, which thus acts as a reservoir. At the top of the incline the bubbles rise into a vertical tube so narrow that each bubble fills its diameter. Each bubble in the vertical tube rapidly overtakes the former ones and draining is so rapid that within a few inches there is a continuous column of cylindrical bubbles in contact with each other. At the height at which draining is found to be sufficiently complete the narrow tube is curved over and down. The films break in the downward portion of the tube, condensing to a liquid, which is caught and analyzed for comparison with the original solution. By changing the degree of inclination of the long, sloping reservoir the bubbles can be kept in contact with the solution for any desired period of time; but in the vertical tube the bubbles must not be allowed to burst

before they have gone round the bend. In the case of the very unstable bubbles from aqueous *p*-toluidine the four seconds during which these films last is ample for this purpose. To forestall a possible source of criticism (see later) the films should be allowed to break within the narrow tube before they reach its exit.

The apparatus is shown in Fig. 2. Nitrogen from a cylinder fitted with a constant pressure regulator is purified by passing through aqueous sodium hydroxide and is then

Fig. 2.—Comparison of absolute adsorption measured by the authors with that calculated from the so-called "Gibbs" (concentration) formula.

saturated with the vapors of the solution which is to be measured, first by bubbling it through a sample of that solution and then by passing it through a Washburn saturator filled with another sample of the same solution for final adjustment. The pressure is steadied by a capillary tube after which the gas bubbles into the apparatus through a suitably designed jet. The bubbles slowly pass up the long, inclined tube and rapidly up the narrower vertical tube, each pushing the previous ones out of the top of the liquid toward the vessel where the liquid from the collapsed films collects. From here the

nitrogen, still saturated with the vapors from the solution, passes through a Parkinson and Gowan flow meter, previously calibrated by passing through it a known volume of air from a large gas holder. It was found that the volumes recorded by this instrument differed from the true values by less than one per cent.

It is essential that the narrow vertical tube be kept thoroughly wet so that bubbles do not break or come into real contact with the glass. For this purpose a further supply of original solution is provided in the supplementary reservoir and this is allowed to flow slowly into the apparatus until the orderly arrangement of bubbles and films has been fully attained. Thereafter, only such solution is supplied as is required to maintain the level of the liquid in the vertical tube constant at the optimum height. The experiment begins when this steady state has been set up; a fresh collecting vessel is put on and the first reading on the flow meter taken. When sufficient nitrogen is passed, that is, when a sufficient volume of liquid from collapsed film has been collected, the bubbling is stopped, the time taken, the flow meter read and disconnected and the collecting vessel stoppered and weighed. About 30 cc. of the solution is allowed to flow out through the narrow tube and collected in a separate vessel. The solution remaining in the inclined tube is all collected in the top reservoir, by applying gentle suction, and well mixed. The three solutions are then each analyzed in duplicate, using a Zeiss refractometer which determines the refractive index to about one division, which corresponds in the case of *p*-toluidine to about 1.49×10^{-6} g. of toluidine per cc. of solution. This is probably the most accurate method of analysis for such binary liquids.

Blank experiments were performed which showed that the method of cleaning and filling the apparatus was efficient, for the samples taken as in an experiment, but without any bubbling, were identical with the original solution. An essential blank experiment is one to show that saturation of the nitrogen is accurate, so that the nitrogen which escapes from the flow meter should neither impoverish nor enrich the solution under investigation as it passes through. For this purpose it was only necessary to allow the gas to pass through as usual but with the level of the liquid in the vertical tube sufficiently lowered so that no films escaped. Under these conditions we found that the concentration of the solution was completely unaffected by the passage of the previously saturated nitrogen. This is of great importance in the final considerations of the results which cannot be ascribed to this possible source of error.

If a thin surface film of toluidine solution of volume v and exposed area s be removed from the reservoir of liquid of original concentration c_0 to the collecting vessel, and if the actual surface contains its equilibrium amount of adsorbed toluidine Γ , then the weight of toluidine in the collecting vessel will be equal to $c_0v + \Gamma s$, and for n such films $c_0nv + \Gamma ns$. The volume of the solution in the collecting vessel V would be nv and its concentration c_1 will be $c_0 + \Gamma ns/v$; whence $\Gamma = [(c_1 - c_0)V]/ns$. In deriving this equation it is assumed that c_0 , the concentration of the solution from which the films were taken, remains unchanged during the removal of the film, whereas in practice a relatively small but finite decrease will occur. If the final concentration of the remaining solution is c_f , then since $c_0 - c_f$ is very small compared with $c_1 - c_0$, then the in-

crease in the concentration c_1 of the solution collected over that in the reservoir will be $c_1 - (c_0 + c_f)/2$ instead of $c_1 - c_0$. Hence $\Gamma = (V/ns) \cdot [c_1 - (c_0 + c_f)/2]$. The detail of the experimental procedure is best illustrated by giving the data of an actual experiment in full.

Experiment 4 of Section V.—Twenty-four minutes were required for this experiment during which the flow meter registered the passage of 0.05 cu. ft. = 1420 cc. The rate of formation of films (or bubbles) was 100 in 74 seconds at the beginning, at the end and throughout the experiment. The time of contact between bubble and solution in the reservoir was 14 seconds, many previous experiments having shown that no further adsorption occurred after 4 seconds, hence a threefold margin of time is always allowed.

The volume of solution collected from collapsed films (weighed) was 38 cc. A further sample of 38 cc. of liquid was allowed to flow out through the vertical tube and 350 cc. remained in the reservoir. The original solution contained 1.000 g. of toluidine per liter and when placed in a 4cm. cell in the interferometer and compared with water produced a change in reading of 640 divisions on the micrometer screw (this deflection being directly proportional to the difference in concentration, one division corresponding to 1.49×10^{-6} g. per cc.). The liquid collected from the collapsed films showed a gain over the original solution of 20 divisions, the sample of liquid taken from the vertical tube likewise showed a gain, although of only one division, showing that the transport of toluidine by the films is not quite complete. This increase was added to the other liquid collected. The final solution in the reservoir showed a loss of between 3 and 4 divisions. Hence, the total change in total concentration of the solutions collected relative to the mean concentration of the initial and final solution in the reservoir is 23 divisions. Hence, the total transport of toluidine = $V[c_1 - (c_0 + c_f)/2] = 38 \times 23 \times 1.49 \times 10^{-6} = 1.3 \times 10^{-3}$ g. The total number of bubbles, n , = 1950. Hence the volume of each bubble is 1420/1950 cc. Each bubble in its final form is a right cylinder of radius 0.65 and, therefore, of length 0.55 centimeters. The total area of these cylindrical bubbles is equal to $1950 \times 2\pi \times 0.65 \times 1.2 = 9550$ square centimeters. Hence $\Gamma = \text{total transport}/ns = 13.6 \times 10^{-8}$ g.

In this particular experiment there was a slight decrease in concentration in the residual solution due to evaporation and loss of toluidine. The total gain in the liquid from the collapsed films is, therefore, rather less than observed in the original solution. In better experiments the two were equal within the experimental error. This is very important because, as has been mentioned, the gain in toluidine is twice as great as that corresponding to a monomolecular film or to that calculated from the so-called Gibbs concentration formula.

The partial pressure of *p*-toluidine above its aqueous solution has been

measured in the Bristol Laboratory by F. H. Pollard. From his results one may deduce that the partial pressure of *p*-toluidine of the solution used above was about 0.0078 mm. at 16°. The total volume of nitrogen passed through, namely, 1420 cc., exactly saturated with this vapor would, therefore, contain 6.6×10^{-5} g. of toluidine. Now the total amount of *p*-toluidine adsorbed and transported in the surface was 129.9×10^{-5} g. Hence, since the total amount of toluidine in the gaseous phase is only a few per cent. of the amount actually transported in the surface of the bubbles, any lack of adjustment in the saturation of the nitrogen with the vapors of the solution must leave the final experimental result of $\Gamma = 13.6 \times 10^{-8}$ g. per sq. cm. almost unaltered.

The Effect of Size of Bubble upon the Value Obtained.—If it is the true value of the adsorption Γ that is obtained by these measurements, they should be independent of the actual surface used. The following series of experiments shows the effect of keeping all other conditions constant and varying only the size of bubbles in the same tube. This appears as a variation in the length of the cylindrical bubbles or in the distance apart of the visible films when the bubbles have drained after coming into contact. The results are collected in Table II.

TABLE II
THE EFFECT OF VARYING THE LENGTH OF BUBBLE UPON THE APPARENT VALUE OF THE ADSORPTION*

Length of cylinder, cm.	Total surface area (sq. cm.)	Γ in g./sq. cm., obs.
5.5	43,000	4.5×10^{-8}
2.5	25,000	8.4×10^{-8}
1.5	19,300	12.7×10^{-8}
1.2	23,000	13.0×10^{-8}
1.1	24,000	14.5×10^{-8}
0.75	17,200	14.8×10^{-8}
.57	12,500	14.7×10^{-8}
.52	15,300	14.9×10^{-8}
.36	13,600	14.5×10^{-8}

* Solution 4 g. toluidine per liter. Internal diameter of the vertical tube 1.30 cm.

The results in Table II, properly interpreted, show the validity of this method of measuring Γ and likewise reveal under what conditions true values are obtained. It is seen that as soon as the cylindrical bubbles are appreciably shorter than their diameter the value of Γ observed is constant and independent of further alteration in the surface area. This is readily understood when we consider the propulsive and retarding forces which act upon a cylindrical bubble passing up a tube. If the bubble is short it will move as a whole. If the bubble is very long in comparison with its diameter the propulsive force is applied to its ends, whereas frictional retarding force is applied to its sides, and if the bubble is long enough the middle part of the cylindrical sides will not move, even al-

though separated from the glass walls by a finite thickness of aqueous solution. In the extreme case there will be a succession of flat films representing the ends of the bubbles pressing up through a tube lined with a film of the same or slightly greater concentration. Hence, in such a case the method cannot be expected to give correct results since the surface taken for the calculation is the whole internal area of the bubble whereas only the ends are actually transporting toluidine. As a check upon this it can be seen that the values for Γ in the last column of Table II become almost constant if it is assumed that only 1.1 cm. of the length of each bubble can actually be moved. Of course there will always be a residual drag which will be reflected in a slightly greater transport if the liquid remaining in the vertical tube is collected and analyzed. In the experiment quoted above this represented 1 division out of 23 expressed in interferometer readings. The length of the bubble usually employed throughout the final measurements was about 0.5 cm. and never exceeded 1 cm. In every experiment it was found that the value for total transport, as calculated from the decrease in concentration of original solution was, within the limits of analytical error, equal to that obtained from the increased concentration of the solution produced from the collapsed films. This is important as proving that the final movements of the bubbles did not extract toluidine from the previously saturated stream of nitrogen passing through. This proves, too, that even though there must be a drag upon any bubble passing through any solution, and hence a tendency towards thinning out or renewal of the forward surface and a corresponding thickening or concentration at the rear surface, the error introduced in the particular substance we have investigated can be only very slight. It might be far otherwise with any substance whose adsorption is quick and desorption slow but if such a substance were volatile, as ours are, the effect would be at once detectable by impoverishment of the gaseous phase which we have shown not to occur in our experiments. This argument is vital to the acceptance of our numerical values. It so happens that the partial pressure of the toluidine above the solutions is such that there is just about as much toluidine in the gaseous phase within each bubble as is adsorbed upon the surface of the bubble. Hence, if the nitrogen were robbed of all its toluidine the observed transport would be doubled, but since this effect did not occur this source of error is measurably absent. In other words, our results can only be a few per cent. too great. For the reason stated no dynamic method can be perfect and the ideal method must be static.

Experimental Results for the Adsorption of *p*-Toluidine in the Nitrogen-Water Interface

Our numerical data are collected in Table III, which gives the results for solutions of *p*-toluidine ranging from 0.6 g. per liter up to saturation.

The two extreme concentrations yield only approximate results because in the most dilute solution the absolute change is small and in the saturated solution the liquid from the collapsed films was supersaturated and before analyses could be carried out a few small crystals of toluidine were observed to separate. Thus the true value must be greater than that actually recorded. Sufficient data are given to show the degree of reproducibility of the experiments and to estimate the approximate error in the results. The toluidine was obtained from Kahlbaum and well recrystallized, m. p. 45.6°. The solubility measured by Edwards was 0.654 g. in 100 cc. of water at 15°. Conductivity water was used as solvent. The temperature was 16°.

Comparison of the Adsorption Observed with the Amount Needed for a Monomolecular Film

It is of course impossible to measure directly the amount of a soluble substance which is required to form a true monomolecular film. There are, however, two other means of estimating the dimensions of the molecule. The first is by comparison with substances higher in the homologous series which are sufficiently insoluble and whose area has been directly measurable by the film method. For example, Adams has found the area covered by a single molecule of hexadecylaniline in a close-packed monomolecular film on water to be 24×10^{-16} sq. cm. and for hexadecylphenol 24×10^{-16} sq. cm., whereas we have found one molecule of toluidine for each 14×10^{-16} sq. cm. of available surface. Even if shorter molecules might be packed slightly more closely than longer ones and even if through competition there were a tendency for the monomolecular film of a soluble material to be rather more closely packed than an insoluble film, the discrepancy is undoubted and clearly points to the conclusion that there is not room on the surface for all of the adsorbed material.

The extent to which molecules in a monomolecular film can be compressed is limited by the dimensions of the molecules themselves and these

are given by x-ray analysis of the solid crystals. The toluidine molecules occupy the minimum area when oriented perpendicular to the surface. The dimensions of molecules containing the benzene ring have been obtained by Bragg using naphthalene⁹ and by Shearer using benzene.¹⁰ From the data for naphthalene it has been concluded that the area of cross section of a benzene ring is 25×10^{-16} sq. cm., while Shearer obtained from the unit cell of benzene itself a cross-sectional area of 23.3×10^{-16} sq. cm. Both of these agree with the dimensions of a single molecule in a monomolecular film but show that if there is one molecule of toluidine for each 14×10^{-16} sq. cm. not much more than half can be upon the actual surface.

The Change of Surface Tension with Concentration

Our measurements have demonstrated that the adsorption is constant over a wide range of concentration and that nevertheless the surface tension continues to fall with increase of concentration even after this constant value has been attained. This requires explanation. At first sight it might have been expected that the surface tension should be constant once the monomolecular film on the surface had been formed and the adsorption was constant. The surface tension as measured experimentally may be regarded as being the sum of the surface tension of the exposed outer surface of the monomolecular film of *p*-toluidine plus the interfacial tension between the film and the solution. This is the expression used by Antonoff¹¹ for the surface tension of a complete film and verified by him for the benzene in water system. The surface tension of the film is taken as constant since the molecules therein have a constant orientation and resemble those in the surface of liquid toluidine in bulk. Hence in applying this conception to the present systems, namely, unsaturated solutions, which are more complicated than the saturated systems hitherto studied, it is necessary to ascribe any change in total surface tensions to change in the interfacial tension between the monomolecular film and the solution upon which it rests.

Morgan and Egloff¹² studied the partially miscible liquids phenol-water and found at saturation the surface tension of each of the two layers was the same as the surface tension of pure phenol. For regions in which only one layer could exist they found that the addition of phenol lowered the surface tension until at saturation it was that of pure phenol. Similar behavior was found with solutions of amyl alcohol and triethylamine. We, therefore, conclude that in our system, aqueous toluidine,

¹¹ Antonoff, *J. chim. phys.*, **5**, 392 (1907). See also Iredale, *Phil. Mag.*, **49**, 466 (1921), who verified this expression for a monomolecular film of water on mercury.

¹² Morgan and Egloff, *THIS JOURNAL*, **38**, 844 (1916).

the saturated solution should have approximately the same surface tension as liquid toluidine, that is, the surface tension of the outside layer of *p*-toluidine molecules. This assumes that in this saturated solution there is no interfacial tension between the film and the aqueous layer. The suggestion thus derived may be summed up in the statement that the more concentrated the solution, the less disparity will exist between it and the monomolecular film on its surface, and the less, therefore, will be its interfacial tension. The interfacial tension will, therefore, decrease with increasing concentration until it becomes vanishingly small for the saturated solution. This decrease in interfacial tension would explain why the experimentally measured surface tension of a solution continues to alter with increase of concentration even after a monomolecular film is formed on the surface, and predicts a definite value toward which surface tension should tend with approach to saturation.

Using the du Noüy tensimeter (inaccurate for such systems) for *p*-toluidine solutions near saturation it was found that within the experimental error the solutions attained a constant value of surface tension. Three solutions containing 5.6, 6.0 and 6.4 g. of toluidine per liter gave each a surface tension of 52.6 dynes. It is interesting to note that the so-called Gibbs theorem would predict zero adsorption for these solutions, whereas the actual adsorption is the same as for the more dilute solutions where the surface tension is changing rapidly with concentration.

It is interesting to speculate as to the depth to which a surface really extends, that is, the depth to which it is different in properties or in concentration from the bulk of the liquid. One has to avoid the dilemma that on the one hand the range of molecular attraction extends only between molecules actually in contact and on the other that the composition of the layer immediately below the monomolecular film is different for each concentration of the solution as is shown by the change in surface tension with change in concentration. We have found that the total weight of excess toluidine associated with one square centimeter of surface is 14×10^{-8} g. Of this possibly 8×10^{-16} g. are in the monomolecular film of pure *p*-toluidine, leaving 6×10^{-8} g. in the adjacent submerged region. Since a saturated solution of *p*-toluidine contains only 6 g. per liter, 6×10^{-8} g. would in itself suffice to saturate a depth of 1×10^{-8} sq. cm., which is what was formerly regarded as within the range of direct molecular attraction. However, since the solution itself already contains anywhere from a few grams up to saturation amount of *p*-toluidine per liter, and this adsorption is additional and constant for all except the most dilute solutions, there is more toluidine concentrated below the surface than could be contained in a saturated solution. However, we do not conceive of these underlayers as supersaturated or even as uniform but explain them in accordance with Fig. 1d as due to the presence of

the chains of *p*-toluidine reaching down deeply into the solution from various isolated points on the under side of the monomolecular layer.

Test of the So-Called Gibbs Theorem $\Gamma = \frac{-c}{RT} \frac{d\sigma}{dc}$

All authors previous to 1925 did not use the true Gibbs theorem but substituted for it the simplified approximation formula given in the heading above in which adsorption is merely referred to as change of surface tension with concentration. Now that we have substantially accurate quantitative results, it is possible to show that this is inadmissible even for the simple crystalloidal substances we have used, namely, toluidine, amyl alcohol and camphor in aqueous solution.

Fig. 3.—Surface tension of aqueous solutions of *p*-toluidine and amyl alcohol carefully measured by the Ferguson method and of camphor using du Nouy tensimeter.

Special care was devoted by P. R. Edwards to obtaining trustworthy values for the surface tension of aqueous solutions of *p*-toluidine. He employed the Ferguson method in which the pressure of air is measured which is required to blow down into a capillary tube inserted in the surface of a solution until the meniscus in the capillary is flat and exactly at the

lower end of the capillary.¹³ Fig. 3 gives the data obtained by Edwards for solutions of *p*-toluidine, each point being the mean of six readings. Fig. 3 shows also Edwards' values for aqueous amyl alcohol by the same method and our values for aqueous camphor¹⁴ using the du Noüy tensiometer with the procedure suggested by Klopsteg.¹⁵ Hence, the values for camphor can only be regarded as semi-quantitative, although consistent.

In calculating the slope of the surface-tension curves it has to be remembered that the slope is not obtained by direct measurement but by the difference in values of isolated measurements of the surface tension itself, that is, small differences between large numbers. However, this source of error is completely eliminated if the comparison of slope with observed adsorption is not confined to a single point but is spread out over a wider range of concentrations.

Fig. 4.—The apparatus employed for the measurement of absolute adsorption in the air-water interface.

In Table IV are given the values calculated by the concentration formula $\Gamma = \frac{-c}{RT} \frac{d\sigma}{dc}$ from the slope of the surface tension curve for comparison with the adsorptions actually observed, $R = 7.843 \times 10^{-8}$ ergs per g. The comparison is still more strikingly made in Fig. 4.

It is evident that although the predictions of the concentration formula are of the right order of magnitude it can only be regarded as being semi-quantitative. The same conclusion results from the fairly good experiments with amyl alcohol and the less exact experiments with solutions

¹³ (a) Edwards, *Trans. Faraday Soc.*, 16, 384 (1921); (b) *J. Chem. Soc.*, 127, 744 (1925).

¹⁴ Although Edwards has published careful measurements of aqueous solutions of camphor his recorded concentrations should be divided by 10 and hence all his solutions are more dilute than those here used.

of camphor now to be described. In all cases we are dealing with crystalloidal non-electrolytes. Hence, the concentration formula must be regarded as only a first approximation.

The Adsorption of Amyl Alcohol and of Camphor in the Air-Water Interface

Iso-amyl alcohol supplied by Kahlbaum and distilling at 130° was employed. On account of its appreciable volatility great care was taken to have the nitrogen passed through the aqueous solution exactly saturated so that when no bubbles or films were allowed to leave the main reservoir the passage of the nitrogen caused no detectable alteration in the concentration of the solution. One division of the interferometer scale corresponded to 3.7×10^{-6} g. per cc. The results of the measurements have been collected in Table V. The values for the most dilute solutions are only approximate because of the small analytical change; amyl alcohol does not affect the refractive index nearly as much as toluidine. The same apparatus was used in all experiments.

* Time of contact of nitrogen and solution varied between 12 and 15 seconds.

A constant value for the adsorption, namely, 16×10^{-8} g./sq. cm. is attained at and above the concentration of 2 g. per liter. This corresponds to one molecule of amyl alcohol for each 9×10^{-16} sq. cm. of surface. Langmuir found that the normal higher insoluble alcohol, hexadecyl alcohol, had an area in monomolecular film of 2×10^{-16} sq. cm. Hence, once more the observed adsorption is definitely greater than the amount which could be accommodated on the surface as a close-packed monomolecular film.

The experiments with camphor are more difficult because of the instability of the bubbles. Hence, a continuous flow of liquid was maintained over the bend at the top of the vertical tube. The camphor used was the best procurable natural Japanese, melting at 177° . One division of the interferometer reading corresponded to 2.7×10^{-6} g. per cc. The results are collected in Table VI.

It will be noted that for solutions whose concentration ranges from 0.5 to 1.3 g. per liter (saturated solution) the adsorption is approximately 10×10^{-8} g. per sq. cm., corresponding to an area of 23×10^{-16} sq. cm. per molecule of camphor.

Tables VII and VIII give the values predicted from the approximate Gibbs concentration theorem for comparison with the observed amounts of adsorption. The data are also given in Fig. 4 showing that the discrepancy is of the same order of magnitude, and in the same direction as in the case of toluidine.

Since the error in the concentration formula is evidently several fold, this explains the results obtained by Langmuir and later workers who in lieu of actual experiment used this formula to obtain values for the adsorption of one molecule of a lower fatty acid for 31×10^{-16} sq. cm. of surface, whereas one molecule can only cover 22×10^{-16} sq. cm. in a complete monomolecular film and presumably the true adsorption is still greater. We hope to present experimental evidence in a further communication. The conclusion is that we must go back to the true equations as actually formulated by Gibbs.

Adsorption and Thermodynamics

The glaring discrepancy between adsorption as actually observed and the predictions of the simplified so-called Gibbs formula $\Gamma = (-c/RT) \cdot (d\sigma/dc)$ makes it necessary to examine the basis upon which the thermodynamic treatment of this subject rests.

The derivation given by Lewis and Randall¹⁶ shows clearly the assumptions now usually made. These are that (1) only two components are present anywhere in the system, and that (2) the only free energy of a surface is its surface tension multiplied by its area. If so, necessarily $\Gamma = -(d\sigma/d\mu)$, where μ is the potential of Gibbs.¹⁷ This may be written $\Gamma = -d\sigma/d\bar{F}$ or $\Gamma = (-a/RT)(d\sigma/da)$ where \bar{F} and a are the partial molal free energy and activity of the solute in Lewis and Randall's nomenclature.

The formula is usually simplified by substituting concentration for activity, with the misleading results which we have previously discussed.

One reason for the disagreement between the facts and the simplified formula is due to the nature of the materials usually chosen. Surface-active substances are usually far from ideal and often of limited solubility, with corresponding deviation from the ideal partial vapor pressure. It should be clearly understood that the potential or activity is that exhibited by the solute in the bulk of the solution and it is not affected by whatever complications occur at the surface; the whole behavior at the surface is governed by the potential within the ordinary homogeneous solution, and the potential of each component in the surface must equal this, no matter how complicated the actual surface may be. For example, a crystalloidal solute might be adsorbed in colloidal form, but its amount would still be that predicted from the properties of the bulk of the solution; however, a solute which was so readily brought into colloidal form would be expected to possess a potential or activity differing from that of an ideal solution.

Reverting to the thermodynamic formulation, the first consideration

¹⁶ Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., 1923, p. 250.

¹⁷ In the notation used by Lewis and Randall, $v_1 = (-d\gamma/d\bar{F}_1)_\sigma$.

that arises is that seldom or never have true, two component systems been actually under observation, although this is fundamental. Solutions of electrolytes or substances capable of hydrolysis, such as soap, cannot be treated as two component systems except in the rare event that the composition of the adsorbed material is identical with that of the solute remaining in the solution. For example, the foam from a neutral soap solution contains acid soap; thus the free alkali remaining in the solution is introduced as a new and important variable component. The numerical data for the adsorption of soap will be dealt with in a later paper; they present the most flagrant conflict with the prediction of the simplified formula, differing in order of magnitude and even in sign.

The component (or components) actually present, but hitherto ignored, is the gas (or air) in presence of which the surface tension is measured and bubbles are produced. For the more general treatment it is simplest to proceed from the original equation. In this subject, number 508 of Gibbs (Scientific Papers, page 230). Gibbs' equation 508 is an application of the first law of thermodynamics, and reads $d\sigma = -\eta_s d\ell - \Gamma_1 d\mu_1 - \Gamma_2 d\mu_2 - \Gamma_3 d\mu_3$, etc., where the subscripts refer to the respective components (for example, Γ_1 water, Γ_2 toluidine and Γ_3 the nitrogen); the first term on the right vanishes for constant temperature. The equation implicitly excludes electrical, etc., effects. It makes the same assumption that the free energy of the surface is given by its surface tension multiplied by its area, but it explicitly mentions each component present in the system. The adsorptions Γ , here referred to by Gibbs are the absolute values, defined as the excess or deficiency of the amount of each component as compared with that which would have been present if the two homogeneous phases (solution and vapor) had extended without alteration up to an arbitrary mathematical dividing surface. This ingenious definition affords a definite value for the adsorption, no matter how deep, stratified or complicated the actual physical surface may be.

The value of Γ for any one component (preferably the solvent) may be set equal to zero by suitably placing the arbitrary mathematical surface. This may be done even if the solvent is actually absent from a layer of the physical surface, as is the case where we have a monomolecular film of solute upon the surface, with solution below and vapor above it. Having set $\Gamma_2 = 0$, the values of Γ_2 and Γ_3 are defined with reference to the solvent. The experiments described correspond with this definition, because they are so carried out that the vapor phase is kept unaltered as the surface is destroyed, and hence the whole of the material in the physical surface goes into the final liquid which is then analyzed for change in concentration relative to the solvent. Lewis and Randall's definition is the same, for they keep the total amount of solvent in the system constant and define Γ_2 as the amount of the second component it is necessary to add when the

surface is increased if the bulk of each phase is to be kept unaltered in properties, such as partial molal free energies, and hence in concentration.

Where there are second and third components (such as *p*-toluidine and nitrogen) their adsorption is $\Gamma_2 = -(\partial\sigma/\partial\mu_2)_{\mu_1}$ and $\Gamma = -(\partial\sigma/\partial\mu_3)_{\mu_1}$, each of which is readily measured, although this has never been done. It is obvious that the two adsorptions will mutually interfere. The gas cannot be quite ignored. For example, it has been stated that the surface tension of mercury is 10% lower in the presence of one atmosphere of nitrogen than *in vacuo*; similarly, nitrogen lowers the surface tension of water by about 1%, which would correspond to the adsorption of about 3% as many molecules of nitrogen as of *p*-toluidine. However, such mutual interference cannot explain the high values of the observed adsorptions.

Several authors such as Donnan⁷ have suggested that the Gibbs theorem applies only to a layer of the surface one or two molecules deep, and that other changes may occur in deeper layers which are not included in the Gibbs equation. This is to forget the strict definitions of Gibbs who in introducing his thermodynamic formula found it essential to include with the surface a layer of the adjacent phases so deep that the boundaries reached into the truly homogeneous phases on both sides. The Gibbs effect is, therefore, the sum total of all concentration changes whether one or very many molecules in depth from the surface.

In the Gibbs equation all electrical effects are expressly excluded. Nevertheless, all surfaces are electrified in that they exhibit electrophoresis, and this is just as prominent in the gas-liquid interface as in any other. Hence, it is necessary to add at least one term (namely, $-edV$, where e is charge and V is electrical potential) to Gibbs' equation even for dealing with surfaces of non-electrolytes. If ions in solution (such as H^+ and OH^-) are not adsorbed in absolutely identical amounts, this in itself adds one more component to the system. The term $-edV$ produces the equation $d\sigma = -edV$ used by Lippmann¹⁸ before Gibbs, when the temperature and the chemical potential are held constant, which is easily done if the composition and electrical potential of the vapor phases are kept constant.

The exact formulation is not quite simple because of the depth and complex structure of the surface layers. For example, Freundlich has demonstrated that the layer in which movement takes place exhibits an electrokinetic potential which bears little or no relation to the total difference in potential of the two homogeneous phases. Hence, the surface is far from behaving as a simple electrical condenser as envisaged by the earlier investigators. This, however, accords with the recent recognition of the fact that the total surface energy of a liquid is not defined entirely by the nature and orientation of the outermost monomolecular layer of

¹⁸ Lippmann, *Ann. chim. phys.*, (V) 5, 494 (1875).

molecules or ions. Great uncertainty exists as to the value or values of the potential difference between phases involving non-electrolytes. It is chiefly a matter of convention¹⁹ that they are usually taken to be between 20 and 50 millivolts, and such experiments as those of Frumkin give values over ten times greater. Even the absolute charges may not be entirely negligible, as is shown by the behavior of thunder clouds in which mere coalescence of drops and diminution of air-water surface produces discharges of the order of one hundred million volts.

A further communication will deal with thermodynamic data for solutions of *p*-toluidine. The experiments here recorded were completed at Bristol University, England, in 1925.

Summary

1. A simple method has been devised for accurately measuring the absolute adsorption at an air-liquid interface and for the first time trustworthy quantitative data have been obtained. Aqueous solutions of *p*-toluidine, amyl alcohol and camphor have been studied.

2. In every case the amounts actually adsorbed are several times greater than that corresponding to a monomolecular film and it is, therefore, concluded that for these solutions of ordinary non-electrolytes over a wide range of concentration of solutions the surface consists of a saturated monomolecular film of solute resting upon a comparatively thick layer of concentrated solution, gradually falling off with depth to the bulk concentration of the solution.

3. The mechanical explanation of this structure is that chains of oriented molecules extend downwards into the solution from the outermost monomolecular film. It is not assumed that there is a wide range of molecular attraction but rather that in effect the same result is produced by chains of contiguous molecules. It was found that many lines of evidence are in agreement with this hypothesis.

4. The so-called concentration formula of Gibbs, as usually quoted, is shown to give erroneous values for adsorption. It is necessary to use the true thermodynamic formula of Gibbs and not only to take into account all the components (usually much more numerous than anticipated) but also to include the electrical effects which universally occur at surfaces but which were not included in the Gibbs equation. Hence, the numerous data which have been calculated by means of the Gibbs concentration formula are shown to be in error.

NOTES

A Convenient Thermostat Heater.—A dependable thermostat heater that does not emit any light, that is perfectly insulated from the bath and that does not corrode and render the water turbid, became necessary in the work of the author. The usual lamps and metallic heating coils failed to meet one or more of these requirements. A capillary thread of mercury worked very successfully on an A. C. line stepped down by a toy transformer, but it was found impractical to make a mercury resistance high enough to go across a 110-volt D. C. line directly. Accordingly, a new heater had to be developed.

The following device met all these needs very satisfactorily. A Pyrex tube about 40 cm. long and 3 mm. bore was bent into a U and filled with fine flake graphite packed tightly by tapping. Contact was made by means of pieces of copper rod, the ends of which were turned down to conical points to increase the area of contact with the graphite and which were held in place by means of spring leads from the binding posts as indicated (see Fig. 1). A heater of these approximate dimensions, now in use, was found to have a resistance of 270 ohms and accordingly has a heating capacity of 45 watts when put on the 110-volt line. On testing the regulation with a Beckmann thermometer, the heater was found to go on and off regularly in an interval of 0.012° . It would be difficult to distribute this lag between the lag of the heater, the stirring, or the sensitivity of the mercury regulator used. In any case, as this degree of regulation was quite ample for the work in hand, no attempt was made to improve it.

This graphite heater is easily made, has given excellent service under the conditions indicated above, and should find application wherever a heater fulfilling these requirements is desirable.

The Computation of Partial Molal Quantities of Binary Solutions.—The method here developed will be particularly useful in those cases in which great accuracy is desired. For a general discussion of partial molal quantities and methods of their calculation the reader is referred to the work of Lewis and Randall.¹

¹ Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923.

Let G be any extensive property of a system consisting of n_1 moles of A and n_2 moles of B. The mole fraction, N_1 , of constituent A is $n_1/(n_1 + n_2)$, and similarly for N_2 . The molal value, G , of an extensive property of the system is by definition

$$G = G/(n_1 + n_2) \quad (1)$$

The corresponding molal quantities of the pure constituents are obtained by equating n_2 or n_1 to zero, respectively. Let us note that

$$n_1 = N_1 n_2 / N_2 \quad (2)$$

The variation of the molal values may be considered as due solely to the change in the number of moles of one of the constituents, the amount of the second constituent being considered constant. Differentiating Equations 1 and 2, respectively, we obtain

$$(dG)_{n_2} = G dn_1 + (n_1 + n_2) dG \quad (3)$$

$$dn_1 = n_2 dN_1 / N_2^2 \quad (4)$$

By definition

$$\bar{G}_1 = dG/dn_1 \quad (5)$$

$$= G + (n_1 + n_2) dG/dn_1 \quad (6)$$

We will now define a new function,

$$\Delta = G - (N_1 \bar{G}_1 + N_2 \bar{G}_2) \quad (7)^2$$

from which

$$dG = d\Delta + \bar{G}_1 dN_1 + \bar{G}_2 dN_2 \quad (8)$$

Substituting the values of G and dG from Equations 7 and 8 into Equation 6 and simplifying,

$$\bar{G}_1 = G_1 + \Delta + N_2 \frac{d\Delta}{dN_1} \quad (9)$$

By means of Equation 9 we may obtain the partial molal quantities from the directly measured molal quantities and a correction term that is small

Fig. 1.

for all solutions that are approximately perfect. The graph of Δ , calculated from the directly measured molal quantities against mole fraction, will in general have one of the following three forms (Fig. 1). (From its definition Δ will be zero for $N = 0$ or 1.) The intercept of the tangent to the curve on the axis of the pure constituent is the difference between the partial molal value and the molal value for the constituent chosen at the

² In certain cases it may be desirable to take an arbitrary constant in place of G_2 .

mole fraction of the point of tangency. This is indicated in the above diagrams.

An accuracy greater than the practicable limit of the previous method may be obtained by the following continuation, if the accuracy of the original data is sufficient to warrant it. Let $y = f(N)$ be an analytical curve which fits that of $\Delta = f(N)$ fairly closely. Treating the deviation $\Delta' = \Delta - y$, in the same way as before, we obtain the equation

$$\bar{G}_1 = G_1 + (y + N_2 dy/dN_1) + (\Delta' + N_2 d\Delta'/dN_1) \quad (10)$$

Equation 10 gives the partial molal value as the sum of the directly measured molal value, a readily computed term, and a quantity which as before can be obtained graphically.

The Saponification of Ethyl Acetate.—It was found that F. Thomas¹ had reported that the velocity of saponification of ethyl acetate by barium hydroxide in aqueous solution is influenced by light. Although the data reported seemed too inaccurate for acceptance, it was desired to ascertain if such variation of intensity of light as may be expected in a laboratory illuminated by diffuse daylight has any effect on the rate of hydrolysis of ethyl acetate in aqueous sodium hydroxide solution. Accordingly, measurements were carried out by me as follows. The technique and apparatus described in a previous paper² were used except that in the first experiment and in each alternate experiment thereafter, the container of the reaction mixture was wrapped in tin foil and the operations of mixing the reagents and of removing the samples of the mixture for analysis were carried out with a dim ruby lamp as the only source of illumination. The respective concentrations of ester and sodium hydroxide were 0.008 and 0.01. The average coefficient found for the reaction in darkness (ten experiments) was 6.77 at 25.00°. The average (eight experiments) for the reaction in diffuse daylight was also 6.77 at 25.00°. It was, therefore, established that variations of intensity of diffuse daylight such as may occur under varying laboratory conditions have no effect on the rate of the reaction in question.

UNSATURATION PHENOMENA OF ACETYLENIC ACIDS AND ESTERS

I. THE CONSTITUTION OF 2-KETO-11-UNDECYLIC ACID

BY WILLIAM WHALLEY MYDDLETON AND ARTHUR WILLIAM BARRETT

RECEIVED APRIL 28, 1927

PUBLISHED SEPTEMBER 2, 1927

The preparation of a keto-undecylic acid has been described by Welander.¹ It was obtained by the action of moderately concentrated sulfuric acid upon 9,10-undecinoic acid. The constitution of the latter is fixed by the fact that it yields azelaic acid on oxidation,² so that Welander's ketonic acid might be either $\text{CH}_3\text{CO}(\text{CH}_2)_8\text{COOH}$ or $\text{CH}_3\text{CH}_2\text{CO}(\text{CH}_2)_7\text{COOH}$.

The constitution might have been settled by submitting the oxime to the Beckmann transformation and proceeding in the manner described by Baruch,³ but Welander failed to effect the Beckmann transformation.

We set out to determine the constitution in a different way, anticipating that the same acid would be obtained by starting with 10,11-undecinoic acid described by Krafft² and called by him dehydro-undecylenic acid. We found that when this acid was treated with sulfuric acid in the manner described by Welander a poor yield of a keto-undecylic acid was obtained melting at 59.5° and forming an oxime melting at $68-69^\circ$.

The constitution of ethyl dehydro-undecylenate is known from the fact that it forms a silver acetylide with alcoholic silver nitrate and the free acid yields sebacic acid on oxidation.² The ketonic acid derived from dehydro-undecylenic acid must therefore be produced by the second of the two following reactions.

No distinctive aldehydic reactions were found for the product or in its ethyl ester.

Welander gives the melting point of his keto-undecylic acid as 49° and describes its oxime as a non-crystallizable oil. It appeared from this that his must be 3-keto-11-undecylic acid.

We then devised a method of preparing the ketonic acid from dehydro-undecylenic acid in better yield. The acetylenic acid was dissolved in

¹ Welander, *Ber.*, 28, 1449 (1895).

² Krafft, *Ber.*, 29, 2232 (1896).

³ Baruch, *Ber.*, 27, 172 (1894).

glacial acetic acid and was warmed on the water-bath at 70° with mercuric acetate. During about five hours a small amount of mercurous acetate separated and was filtered off. The solution was poured into twice its volume of water and a solid separated. Recrystallization from dil. acetic acid gave a product of definite composition in the form of microcrystalline, colorless needles.

Analysis showed the crystals to be the mercuric salt of a triacetoxymercuri-keto-undecylic acid. Treatment with moderately concd. hydrochloric acid gave a quantitative yield of the keto-undecylic acid melting at 59.5°. To obtain good yields from the dehydro-undecylenic acid it was found unnecessary to isolate the mercury compound, but the whole of the acetic acid solution was treated with mineral acid and the mixture then poured into water.

The analysis of the mercury compound was carried out in three stages. The mercury was estimated by precipitation as mercuric sulfide, hydrogen sulfide being passed through an acetic acid solution containing a weighed amount of the substance. The acetoxy group was determined on a quantity of the substance, dried for several days in a vacuum desiccator at the pump, by suspending a weighed amount in lime-dried absolute alcohol and distilling from a water-bath after addition of concd. sulfuric acid. Ethyl acetate was estimated in the distillate by quantitative hydrolysis. The keto-undecylic acid was liberated from a third quantity by hydrochloric acid, extracted with ether and weighed.

The analyses fix the constitution as $(\text{CH}_3\text{COOHg})_3\text{C.CO}(\text{CH}_2)_8\text{COO}(\text{Hg})^{1/2}$.

We then attempted to prepare Welander's ketonic acid from 9,10-undecinoic acid by the intermediate formation of a mercuric compound. The product gave analyses for the mercuric salt of a diacetoxymercuri-keto-undecylic acid. Treatment with hydrochloric acid gave a ketonic acid which melted at 49–50°. This appeared to be Welander's acid which melted at 49°. Systematic recrystallization from petroleum ether (b. p. 60–80°) led to the isolation of two pure ketonic acids having the molecular formula $\text{C}_{11}\text{H}_{20}\text{O}_3$, one melting at 59.5° identical with that prepared from dehydro-undecylenic acid, and the second melting at 43.5°. The first was obtained in fair amount but less than 1 g. of the second was isolated after recrystallization 18 times. The original 9,10-undecinoic acid melts at 59.5° but analysis and the melting point of a mixture (45–50°) showed that the two substances melting at 59.5° were not identical.

We then repeated Welander's preparation by means of sulfuric acid and obtained a product melting at 48–49°. On repeated systematic recrystallization from petroleum ether we were again able to separate two ketonic acids melting at 59.5 and 43.5° in roughly the same proportions.

It still remained to show that the predominating high-melting con-

stituent in the mixture did not result from the presence of dehydro-undecylenic acid in the 9,10-undecylenic acid used, since both of these acetylenic acids are prepared by the action of potassium hydroxide upon 1,2-dibromo-11-undecylenic acid² at different temperatures. Our next step was therefore to prepare pure specimens of the ethyl esters of the two acetylenic acids by repeated fractionation in a vacuum. Ethyl dehydro-undecylenate is precipitated from alcoholic solution as a silver acetylide by adding alcoholic silver nitrate, and we found that any quantity of this ester greater than 1% present in admixture with ethyl 9,10-undecylenate could be detected by the formation of a precipitate in this reaction.

A quantity of ethyl 9,10-undecylenate which failed to show turbidity with silver nitrate was dissolved in glacial acetic acid and treated with mercuric acetate. The mercury compound was isolated as before. It gave analyses for the ethyl ester of a diacetoxymercuri-keto-undecylenic acid, $(\text{CH}_3\text{COOHg})_2\text{C}_{10}\text{H}_{17}\text{OCOOC}_2\text{H}_5$.

Hydrochloric acid liberated an ester which was separated into two fractions by distillation under diminished pressure. The higher-boiling fraction, distilling at 169–170° (corr.) (12 mm.), represented about 50% of the original ester and gave on hydrolysis the ketonic acid melting at 59.5°. The lower-boiling fraction appeared with progressive rise in temperature from 158 to 169° and gave on hydrolysis a mixture from which a further amount of the acid melting at 59.5° and a small amount of that melting at 43.5° were separated by crystallization from petroleum ether.

On the evidence so far obtained, the acid melting at 59.5° must be 2-keto-11-undecylenic acid and that melting at 43.5° 3-keto-11-undecylenic acid.

We have succeeded in submitting the oxime of the former to the Beckmann transformation under the influence of concd. sulfuric acid. When the product was heated in a sealed tube with concd. hydrochloric acid it yielded almost the calculated amount of sebacic acid.

Experimental Part

Preparation of 1,2-Dibromo-11-undecylenic Acid.—Petroleum ether (b. p. 60–80°) was treated with excess of bromine at room temperature and the mixture allowed to stand for two days. It was then washed with a solution of sodium bisulfite and dried. After distillation the purified product was used as solvent. One hundred and seventy g. of undecylenic acid (m. p. 24.5°; b. p. 168.3° at 15 mm.) was dissolved in 500 cc. of purified solvent. One hundred and fifty g. of bromine was added during one and one-half hours while cooling in a mixture of ice and salt. When about three quarters of the bromine had been added the dibromo acid began to separate. Efficient stirring was required from this point. When the whole of the bromine had been added the mixture was allowed to stand for an hour. The precipitate was filtered off at the pump and washed with 100 cc. of cold petroleum ether. The cake was broken up and transferred to a vacuum desiccator and the excess of bromine and solvent was removed during 24 hours. The white crystals melted at 38.5°; yield, 250 g. The rest of the dibromo derivative was obtained as an oil after washing the filtrate with a solution of sodium

bisulfite, drying and evaporating. The yield of oil was approximately the same in a number of brominations.

Anal. Calcd. for $C_{11}H_{20}O_2Br_2$: Br, 46.5; equiv. wt., 344. Found: Br, 46.2; equiv. wt. (titration against standard alkali), 345.1.

Preparation of Dehydro-undecylenic Acid and 9,10-Undecynolic Acid.—Dehydro-undecylenic acid was prepared from the dibromo acid by the method of Krafft.³ The constants of the substance given by this author were confirmed. 9,10-Undecynolic acid was obtained from the dibromo acid by the method of Welander.¹ The constants described by Welander were confirmed.

Conversion of the Acetylenic Acids into Esters.—The method of esterification at first employed was that described by Krafft³ in which the acid is boiled under a reflux condenser with alcohol and an excess of potassium carbonate. The filtered solution containing the potassium salt was heated in pressure bottles with excess of ethyl iodide. Finally it was found to be less troublesome to reflux the acid with ten times its weight of lime-dried absolute alcohol and its own weight of concd. sulfuric acid. The mineral acid was mixed with the alcohol and the acetylenic acid added when cold. The solution was allowed to stand at room temperature before refluxing for ten hours. At the end of this time the solution was cooled and ether added. After shaking with water the ethereal solution was separated, washed with dil. sodium carbonate solution and water, dried and evaporated. The residue after distillation of the ether was fractionated under diminished pressure. The esters were collected at the following temperatures: ethyl dehydro-undecylenate, 145° (15 mm.), and ethyl 9,10-undecynolate, 197° (49 mm.).

Small quantities of the pure esters were hydrolyzed and gave the following acids: dehydro-undecylenic acid, m. p., 43° ; 9,10-undecynolic acid, m. p., 59.5° .

Treatment of Dehydro-undecylenic Acid with Mercuric Acetate.—Ten g. of dehydro-undecylenic acid was dissolved in 25 cc. of glacial acetic acid in a 500cc. flask fitted with an air condenser. To this was added a solution of 39 g. of mercuric oxide in 225 cc. of glacial acetic acid. The flask was heated on the water-bath at 70 to 100° for five hours. At the end of this time the deposit of mercurous acetate was filtered off while hot and the solution cooled and poured into 250 cc. of water. The solid which separated was filtered off and recrystallized from 75% acetic acid. The colorless microcrystalline needles were drained at the pump, dried on filter paper and finally washed with ether and dried in the vacuum desiccator for at least two days on the pump. There were obtained about 1.5 g. of mercurous acetate and 45 g. of the mercuric compound.

Treatment of 9,10-Undecynolic Acid with Mercuric Acetate.—Ten g. of the acetylenic acid treated as in the preceding case with 28 g. of mercuric oxide in 250 cc. of glacial acetic acid gave a small amount of mercurous acetate and 37 g. of the mercuric compound in colorless, microcrystalline needles.

Treatment of Ethyl 9,10-Undecynolate with Mercuric Acetate.—Thirty-three g. of the ethyl ester which gave no precipitate with alcoholic silver nitrate was treated as described above with 70 g. of mercuric oxide in 500 cc. of glacial acetic acid. About 4 g. of mercurous acetate was separated, and on pouring the filtrate from this into water the product separated as a thick, amber-colored, viscous oil which solidified when shaken with water. The solid crystallized from 75% acetic acid in the form of fine needles; yield, 95 g.

Treatment of Ethyl Dehydro-undecylenate with Mercuric Acetate.—Thirty g. of the ester was treated in 600 cc. of glacial acetic acid with 95 g. of dissolved mercuric oxide. The procedure was the same as that described above.

Analysis of the Mercuric Compounds

1. **Estimation of Mercury.**—Approximately 0.5 g. of the substance was dissolved in hot glacial acetic acid and the solution saturated with

hydrogen sulfide. Concd. hydrochloric acid was then added and the precipitated mercuric sulfide filtered through a Gooch crucible, washed with ether, dried and weighed.

2. **Estimation of Acetoxy Group.**—Approximately 1.5 g. of the substance was weighed and transferred to a distilling flask, the side tube of which was bent downwards at the middle of its length to make an angle of 120° . The flask was fitted with a dropping funnel and was attached to a Liebig condenser. Fifty cc. of absolute alcohol (lime-dried) mixed with 10 cc. of concd. sulfuric acid was admitted through the funnel and the flask was then heated on the water-bath and wrapped round with a duster. The distillate was collected in excess of standard 0.5 *N* alcoholic potassium hydroxide solution, and dry absolute alcohol was dropped into the flask at the same rate as that of the distillation. Fifty cc. of alcohol was added in this way and then the contents of the flask were allowed to distil to about 30 cc. The distillate was refluxed for 40 minutes and the excess of alkali titrated with 0.5 *N* acid. After each titration the solution was evaporated almost to dryness. One portion was treated for the recognition of potassium acetate and the second was diluted with water and acidified to ascertain that no turbidity appeared.

3. **Estimation of the Ketonic Acid or Ester Liberated by Treatment with Hydrochloric Acid.**—Approximately 5.0 g. of the substance was warmed with moderately concd. hydrochloric acid and the mixture then diluted with water. Esters were shaken in a flask with dil. acid, cold. No precipitate of mercurous chloride formed. The ketonic compound was extracted with ether and weighed after being washed and the solvent distilled. The residue was dried before weighing by adding a few drops of absolute alcohol and blowing out the flask at the bellows while immersed in boiling water. Two or three treatments in this way served

TABLE I
RESULTS OF THE ANALYSES

Initial acetylenic compd.	Analysis of mercuric compound		
	Hg, %	CH ₃ COO, %	Ketonic compd., %
Dehydro-undecylenic acid, found	65.2	16.3	18.5 C ₁₁ H ₂₀ O ₂
Calcd. for mercuric 1-triacetoxy-mercuri-2-keto-11-undecylate	65.3	16.5	18.6 C ₁₁ H ₂₀ O ₂
9,10-undecynolic acid (found)	61.4	14.4	24.3 C ₁₁ H ₂₀ O ₂
Calcd. for a mercuric diacetoxymercuri-keto-undecylate	61.4	14.5	24.5 C ₁₁ H ₂₀ O ₂

to bring the flask to constant weight. The analyses of the ketonic compounds thus obtained are described later.

Preparation of the Ketonic Compounds without Isolation of Mercuric Compounds.—Almost quantitative yields of the ketonic compounds were obtained from the acetylenic acids and esters by treating with the amounts of mercuric oxide and acetic acid stated and then adding concd. hydrochloric acid to the whole of the solution and pouring into water. The solid separating was filtered off and then treated with ether to separate from mercurous acetate. The filtrate was extracted with ether, the ether distilled and acetic acid blown off at the bellows or distilled under diminished pressure. The products were, if solid, recrystallized from petroleum ether. Esters were extracted with ether after being poured into water and fractionated under diminished pressure.

Properties of 2-Keto-11-undecylic Acid.—The acid crystallized in fine tufts of colorless needles or in small glistening leaflets. No regularity has been observed in the occurrence of these two forms. The crystals melt sharply at 59.5° . They are moderately soluble in hot petroleum ether (b. p. $60-80^{\circ}$) and practically insoluble in cold. They are slightly soluble in boiling water and almost insoluble in cold. The solubility in other organic solvents is considerable.

Anal. Calcd. for $C_{11}H_{20}O_3$: C, 65.95; H, 10.00; equiv. wt., 200.16. Found: C, 65.89; H, 10.17; equiv. wt. (titration with standard alkali), 200.

The ethyl ester boils at $169-170^{\circ}$ (corr.) (12 mm.). It gives no indication of enolization. The semicarbazone, prepared by adding a solution of semicarbazide hydrochloride with slightly more than the equivalent amount of sodium acetate to a solution of the acid in dil. alcohol, melts at 136.5° (corr.) after recrystallization from alcohol.

Anal. Calcd. for $C_{13}H_{22}O_3N_2$: C, 55.99; H, 9.01; N, 16.34. Found: C, 55.91; H, 9.08; N, 16.27.

The oxime prepared in the usual manner melts at $68-69^{\circ}$. When warmed on the water-bath for an hour with five times its weight of concd. sulfuric acid and then poured into water it is converted into a mixture of the isomeric acids $CH_3NHCO(CH_2)_8COOH$ and $CH_3CONH(CH_2)_8COOH$, melting after recrystallization from alcohol between 65 and 72° .

Anal. Calcd. for $C_{11}H_{21}O_2N$: C, 61.34; H, 9.84; N, 6.51. Found: C, 61.30; H, 9.91; N, 6.38.

Anal. (oxime). Found: C, 61.26; H, 9.90; N, 6.47.

Ten g. of the mixed acids after the Beckmann change was heated with 30 cc. of hydrochloric acid solution (saturated at room temperature) for five hours at $180-190^{\circ}$ in a sealed tube. The contents were washed into a flask and steam distilled for 30 minutes. The contents of the flask were made alkaline and again steam-distilled for 30 minutes. The residue in the flask was concentrated to 100 cc. and acidified. Crystals separated and these were recrystallized from water. They melted at 134° and were recognized as sebacic acid by the mixed melting point of 134° with sebacic acid derived from the oxidation of dehydro-undecylenic acid. The yield of sebacic acid was 4 g.

The oxime was found to give an almost quantitative yield of 2-keto-11-undecylic acid on hydrolysis with dil. sulfuric acid.

The authors are indebted to the Government Grant Committee of the

hydrogen sulfide. Concd. hydrochloric acid was then added and the precipitated mercuric sulfide filtered through a Gooch crucible, washed with ether, dried and weighed.

2. **Estimation of Acetoxy Group.**—Approximately 1.5 g. of the substance was weighed and transferred to a distilling flask, the side tube of which was bent downwards at the middle of its length to make an angle of 120° . The flask was fitted with a dropping funnel and was attached to a Liebig condenser. Fifty cc. of absolute alcohol (lime-dried) mixed with 10 cc. of concd. sulfuric acid was admitted through the funnel and the flask was then heated on the water-bath and wrapped round with a duster. The distillate was collected in excess of standard 0.5 *N* alcoholic potassium hydroxide solution, and dry absolute alcohol was dropped into the flask at the same rate as that of the distillation. Fifty cc. of alcohol was added in this way and then the contents of the flask were allowed to distil to about 30 cc. The distillate was refluxed for 40 minutes and the excess of alkali titrated with 0.5 *N* acid. After each titration the solution was evaporated almost to dryness. One portion was treated for the recognition of potassium acetate and the second was diluted with water and acidified to ascertain that no turbidity appeared.

3. **Estimation of the Ketonic Acid or Ester Liberated by Treatment with Hydrochloric Acid.**—Approximately 5.0 g. of the substance was warmed with moderately concd. hydrochloric acid and the mixture then diluted with water. Esters were shaken in a flask with dil. acid, cold. No precipitate of mercurous chloride formed. The ketonic compound was extracted with ether and weighed after being washed and the solvent distilled. The residue was dried before weighing by adding a few drops of absolute alcohol and blowing out the flask at the bellows while immersed in boiling water. Two or three treatments in this way served

TABLE I
RESULTS OF THE ANALYSES

Initial acetylenic compd.	Analysis of mercuric compound		
	Hg, %	CH_3COO , %	Ketonic compd., %
Dehydro-undecylenic acid, found	65.2	16.3	18.5 $\text{C}_{11}\text{H}_{20}\text{O}_2$
Calcd. for mercuric 1-triacetoxy-mercuri-2-keto-11-undecylate	65.3	16.5	18.6 $\text{C}_{11}\text{H}_{20}\text{O}_2$
9,10-undecynolic acid (found)	61.4	14.4	24.3 $\text{C}_{11}\text{H}_{20}\text{O}_2$
Calcd. for a mercuric diacetoxymercuri-keto-undecylate	61.4	14.5	24.5 $\text{C}_{11}\text{H}_{20}\text{O}_2$
Ethyl dehydro-undecylenate, found	59.9	17.3	22.6 $\text{C}_{11}\text{H}_{20}\text{O}_2$
Calcd. for ethyl triacetoxy-mercuri-2-keto-11-undecylate	60.0	17.6	22.7 $\text{C}_{11}\text{H}_{20}\text{O}_2$
Ethyl 9,10-undecynolate, found	53.8	15.6	30.4 $\text{C}_{12}\text{H}_{24}\text{O}_2$
Calcd. for an ethyl diacetoxy-mercuri-keto-undecylate	53.8	15.8	30.6 $\text{C}_{12}\text{H}_{24}\text{O}_2$

to bring the flask to constant weight. The analyses of the ketonic compounds thus obtained are described later.

Preparation of the Ketonic Compounds without Isolation of Mercuric Compounds.—Almost quantitative yields of the ketonic compounds were obtained from the acetylenic acids and esters by treating with the amounts of mercuric oxide and acetic acid stated and then adding concd. hydrochloric acid to the whole of the solution and pouring into water. The solid separating was filtered off and then treated with ether to separate from mercurous acetate. The filtrate was extracted with ether, the ether distilled and acetic acid blown off at the bellows or distilled under diminished pressure. The products were, if solid, recrystallized from petroleum ether. Esters were extracted with ether after being poured into water and fractionated under diminished pressure.

Properties of 2-Keto-11-undecylic Acid.—The acid crystallized in fine tufts of colorless needles or in small glistening leaflets. No regularity has been observed in the occurrence of these two forms. The crystals melt sharply at 59.5° . They are moderately soluble in hot petroleum ether (b. p. $60-80^{\circ}$) and practically insoluble in cold. They are slightly soluble in boiling water and almost insoluble in cold. The solubility in other organic solvents is considerable.

Anal. Calcd. for $C_{11}H_{20}O_3$: C, 65.95; H, 10.00; equiv. wt., 200.16. Found: C, 65.89; H, 10.17; equiv. wt. (titration with standard alkali), 200.

The ethyl ester boils at $169-170^{\circ}$ (corr.) (12 mm.). It gives no indication of enolization. The semicarbazone, prepared by adding a solution of semicarbazide hydrochloride with slightly more than the equivalent amount of sodium acetate to a solution of the acid in dil. alcohol, melts at 136.5° (corr.) after recrystallization from alcohol.

Anal. Calcd. for $C_{13}H_{22}O_2N_2$: C, 55.99; H, 9.01; N, 16.34. Found: C, 55.91; H, 9.08; N, 16.27.

The oxime prepared in the usual manner melts at $68-69^{\circ}$. When warmed on the water-bath for an hour with five times its weight of concd. sulfuric acid and then poured into water it is converted into a mixture of the isomeric acids $CH_3NHCO(CH_2)_8COOH$ and $CH_3CONH(CH_2)_8COOH$, melting after recrystallization from alcohol between 65 and 72° .

Anal. Calcd. for $C_{11}H_{21}O_2N$: C, 61.34; H, 9.84; N, 6.51. Found: C, 61.30; H, 9.91; N, 6.38.

Anal. (oxime). Found: C, 61.26; H, 9.90; N, 6.47.

Ten g. of the mixed acids after the Beckmann change was heated with 30 cc. of hydrochloric acid solution (saturated at room temperature) for five hours at $180-190^{\circ}$ in a sealed tube. The contents were washed into a flask and steam distilled for 30 minutes. The contents of the flask were made alkaline and again steam-distilled for 30 minutes. The residue in the flask was concentrated to 100 cc. and acidified. Crystals separated and these were recrystallized from water. They melted at 134° and were recognized as sebacic acid by the mixed melting point of 134° with sebacic acid derived from the oxidation of dehydro-undecylenic acid. The yield of sebacic acid was 4 g.

The oxime was found to give an almost quantitative yield of 2-keto-11-undecylic acid on hydrolysis with dil. sulfuric acid.

The authors are indebted to the Government Grant Committee of the

Royal Society for a grant which defrayed part of the cost of the investigation.⁴

Summary

1. Crystalline compounds containing mercury are produced by the action of mercuric acetate in acetic acid solution upon dehydroundecylenic and 9-10 undecinic acids and upon their ethyl esters.

2. The mercury compounds yield, after treatment with hydrochloric acid, saturated ketonic acids or esters free from mercury. Hydration at the triple bond has thus been effected.

3. Hydration in the case of dehydroundecylenic acid takes place in one direction, but in the case of 9-10 undecinic acid in the two theoretically possible directions with formation of two isomeric ketonic acids. The ethyl esters behave in the same manner.

UNSATURATION PHENOMENA OF ACETYLENIC ACIDS AND ESTERS

II. THE REACTION BETWEEN MERCURIC ACETATE AND SOME ACETYLENIC ACIDS AND ESTERS

BY WILLIAM WHALLEY MYDDLETON, RUDOLPH G. BERCHEM AND ARTHUR W. BARRETT

RECEIVED MAY 16, 1927

PUBLISHED SEPTEMBER 2, 1927

Two of the present authors have described the isolation of mercury compounds resulting from the action of mercuric acetate upon dehydroundecylenic acid and 9,10-undecinic acid.¹

These examples include one case in which the acetylenic bond is at the end of a carbon chain and one in which it occurs along the chain and without any associated hydrogen atom.

In the present investigation we have varied the type of acetylenic acid by studying the action of mercuric acetate upon (a) stearic acid, (b) ricinolic acid, (c) behenic acid, (d) methyl behenolate, (e) γ -butinene- α,α -dicarboxylic acid, (f) γ -butinene- α -carboxylic acid.

Preparation of the Acetylenic Acids

A preliminary investigation of the methods of preparation of stearic, ricinolic and behenic acids was considered desirable. They are obtained by brominating oleic, ricinoleic and erucic acids, respectively, the

⁴ Since this work was completed the authors have noted that Chuit, Boelsing, Hausser and Malet [*Helv. chim. Acta*, 9, 1074 (1926)] describe the preparation of 2-keto-11-undecydic acid by oxidation of undecane-2,11-diol. The melting point recorded by these investigators is 58.5-59.5°.

¹ Myddleton and Barrett, *THIS JOURNAL*, 49, 2258 (1927).

dibromo acids so formed being then heated with concd. alcoholic or aqueous potassium hydroxide at temperatures between 150 and 180°. The purification of oleic acid and ricinoleic acid is extremely tedious, but it was found unnecessary to arrive at extreme purity in order to obtain the pure acetylenic acids.

(a) **Stearolic Acid.**—The oleic acid for this preparation was derived from olive oil. Analysis had shown that the mixed fatty acids from this oil contain 14.6% of palmitic acid, 10% of linoleic acid and 75.4% of oleic acid.²

It was found sufficient to remove all but traces of palmitic acid by converting the total mixed acids into lead salts and extracting the lead oleate and linoleate with ice-cold ether. The acids regenerated by dil. sulfuric acid were converted into the lithium salts by boiling with an excess of lithium carbonate suspended in water. The lithium salts were recrystallized once from dil. alcohol. Oleic acid of sufficient purity was obtained from the less soluble fraction.

(b) **Ricinolic Acid.**—Castor oil used for the preparation of ricinoleic acid was found to contain 8% of stearic acid, 1% of dihydroxy-stearic acid, 7% of linolenic acid and 84% of ricinoleic acid. In view of this analysis the preparation of ricinolic acid employed by Mangold³ by direct bromination of castor oil followed by treatment of the bromo-glycerides with alkalis was considered unsound.

Stearic acid, therefore, was separated, together with the dihydroxy acid, through the insolubility of their lead salts in dry ether. Ricinoleic and linolenic acids were regenerated from the soluble lead salts and were either converted into lithium salts and recrystallized or into methyl esters and fractionally distilled. The less soluble lithium salt and the methyl ester fraction boiling at 225–227° (10 mm.) gave a sufficiently pure ricinoleic acid.

(c) **Behenolic Acid.**—Rape oil gave a mixture of fatty acids containing 98.8% of erucic acid and traces of lignoceric and arachidic acids. In this case it was found sufficient to brominate the whole of the mixed acids after hydrolysis or to brominate the oil without prior treatment.

(d) and (e) **γ -Butinene-carboxylic Acids.**— γ -Butinene- α,α -dicarboxylic acid and γ -butinene- α -carboxylic acid were prepared in a pure condition by the method described by Perkin and Simonsen.⁴

Action of Mercuric Acetate

The acetylenic compounds were dissolved in glacial acetic acid and warmed on the water-bath with a solution of mercuric oxide in the same

solvent. Reaction proceeded at temperatures between 70 and 100° with deposition of small amounts of mercurous acetate.

The mercury compounds were isolated by cooling the filtered solution and diluting with water. The butinene derivatives were exceptional in yielding relatively large amounts of mercurous acetate and a further product which proved to be a mixture of mercurous and mercuric salts of indefinite composition and from which no ketonic acid could be obtained. The acetylenic acids of higher molecular weight gave mercuric salts of diacetoxymercuri-ketonic acids in the form of microcrystalline needles. These salts were recrystallized from dil. acetic acid. They were found to be decomposed by hydrogen sulfide and hydrochloric acid with formation of ketonic acids.

Methyl behenolate gave the ester of a diacetoxymercuri-ketobehenic acid and this, after being shaken with cold dil. hydrochloric acid, gave a methyl ketobehenate.

In the preparation of ketonic acids it was found unnecessary to isolate the mercury compound. The whole of the acetic acid solution was treated with an excess of concd. hydrochloric acid and the mixture poured into water. The ketonic acid separated in good yield.

Analysis of the Mercuric Compounds

The method employed in the analysis of the mercury compounds is described in detail in the first paper.¹ The results obtained were as follows.

TABLE I
ANALYSES

Acetylenic compound	Mercury compound		
	Hg, %	CH ₃ COO, %	Ketonic acid or ester, %

sulfuric acid upon stearolic, ricinolic and behenolic acids and have described the isolation of ketonic acids as products of the reaction. The constitution of the ketonic acid was in each case established by forming the oxime and effecting scission through the Beckmann transformation. Stearolic acid gave 10-ketostearic acid, ricinolic acid gave 10-keto-12-hydroxystearic acid and behenolic acid gave 14-ketobehenic acid.

We have prepared the ketonic acids by this method as well as by intermediate formation of acetoxymercuri compounds and find that the products are identical. The melting points of the ketonic acids and the parent acetylenic acids are given in Table II.

TABLE II
MELTING POINTS OF KETONIC ACIDS

Acetylenic acid	M. p., °C.	Ketonic acid, m. p., °C.	Method of formation or observer
Stearolic acid	48.0	75-76	Mercury compd.
	48.0	76	Baruch
Ricinolic acid	53.5	84-85	Mercury compd.
	53.0	84-85	Goldsobel
	51.0	78-80	Mangold
Behenolic acid	57.5	83-84	Mercury compd.
	57.5	83	Holt and Baruch

In view of the observation of Myddleton and Barrett¹ that 9,10-undecynolic acid yields a mixture of two ketonic acids, and considering also the suggestion of Robinson and Robinson² that hydration of a triple bond may take place in each of the two possible directions, we submitted the ketonic acids prepared from the mercury compounds to the process of purification described by Robinson and Robinson. The melting points of the purified acids were as follows: 10-ketostearic acid, 76°; 10-keto-12-hydroxystearic acid, 85.6°; 14-ketobehenic acid, 84.5°.

The last two observers we have mentioned found that by treating stearolic acid with concd. sulfuric acid and then pouring into water, according to the method of Baruch, they obtained a mixture of ketonic acids from which, after a troublesome and wasteful process of purification, it was possible to isolate a small amount of a ketostearic acid melting at 83°. The high-melting acid was obtained in better yield by dissolving stearolic acid in concd. sulfuric acid and exposing the solution to moist air in an open vessel. They assume that the acid they have isolated is 10-ketostearic acid because it is indistinguishable from the product of a synthesis which seems capable of yielding only 10-ketostearic acid. We were not able to raise the melting point of our ketostearic acid above 76° by careful purification. This fact, together with the observation of Behrend³ that a ketostearic acid whose oxime yields scission products indicative of

¹ Robinson and Robinson, *J. Chem. Soc.*, 127, 176 (1925); 128, 2204 (1926).

³ Behrend, *Ber.*, 29, 806 (1896).

the constitution 9-ketostearic acid melts at 83° , suggests the advisability of studying the oximes of the acids described by Robinson and Robinson. They have themselves suggested that 9-ketostearic acid is one of the products of hydration of stearolic acid.

According to the constitutions assigned to the ketonic acids under discussion by Baruch, Goldsobel and Holt the keto group occurs at carbon atoms of even number, counting the carboxyl carbon atom as one. The position of the acetylenic bond before hydration is thus fixed to two possible positions, either immediately preceding or following the keto group.

In the case of stearolic, ricinolic and behenolic acids we have found it impossible to isolate from each more than one ketonic acid after hydration but it is possible that very small amounts of a second may be formed. Myddleton and Barrett have found evidence of hydration in two directions in the case of 9,10-undecynolic acid. In such a case the constitution of the two ketonic acids would afford conclusive evidence of the position of the triple bond in the parent acid, but in this instance simpler and equally convincing evidence is found in the fact that dehydro-undecylenic acid which has the triple bond in the ultimate position yields the same ketonic acid.

It is in most cases impossible to determine the position of the original triple bond by reference to the constitution of one ketonic acid derived from the acetylenic compound. Account must necessarily be taken of the nature of the dibasic acid produced by oxidation of the acetylenic acid with such reagents as nitric acid and alkaline potassium permanganate, although this is decidedly unsatisfactory because the dibasic acid is usually formed in small amount.

It is probably safer to derive supporting evidence from the nature of the scission products of the ozonides of the ethylenic acid which may readily be prepared by reducing the acetylenic compound with zinc in the presence of titanous chloride.

We propose to continue the investigation of the mercury compounds we have described to ascertain the position of the acetoxymercuri groups. If this is achieved another method of deciding the position of triple bonds in acetylenic acids and esters will be available.

Experimental Part

Bromination of Oleic, Ricinoleic and Erucic Acids.—The procedure was the same in the three cases. The acid was dissolved in a small volume of glacial acetic acid and a solution of bromine in acetic acid was stirred in at a temperature of 5° until excess bromine was indicated by starch-iodide paper after an hour's interval. The solution was allowed to stand overnight in the ice chest, after which it was poured into a large volume of water. The oily layer was washed with cold water and then with warm

water and finally with a dilute solution of sodium thiosulfate. After a final washing, the product was dried over calcium chloride. In the case of erucic acid the drying was omitted and the semi-solid product recrystallized from alcohol. Rape oil brominated in a similar manner gave a viscous oil which was dried over calcium chloride.

The characteristics of the products were as follows: oleic acid and ricinoleic acid gave a viscous oil; erucic acid gave a solid which after recrystallization from alcohol melted at 42–43°.

Conversion of Dibromo Acids into Acetylenic Acids.—Each dibromo acid was heated to gentle boiling in a solution of twice its weight of potassium hydroxide in eight times its weight of alcohol. For the treatment of brominated rape oil twice the proportion of alkali and alcohol was used. The reaction was complete after seven or eight hours' refluxing in a capacious flask heated in an oil-bath.

The bulk of the alcohol was then slowly distilled, the residue dissolved in water and the solution acidified with hydrochloric acid. The oily layer which separated was induced to crystallize by skimming off and stirring with fresh water.

Action of Mercuric Acetate upon the Acetylenic Acids.—The reaction was carried out as already described with the following amounts of reactants and solvent: acetylenic acid, 1 mole; mercuric oxide, 2.6 moles dissolved in five times the total weight of acetic acid. Methyl behenolate required the following proportions: ester, 1 mole; mercuric oxide, 2.1 moles dissolved in five times the total weight of acetic acid.

The products were recrystallized from 75 to 50% acetic acid.

The authors are indebted to the Government Grant Committee of the Royal Society for a grant which defrayed part of the cost of the investigation.

Summary

1. Mercuric acetate reacts with stearolic, ricinolic and behenolic acids in acetic acid solution to form crystalline mercuric salts of diacetoxymercuri-ketonic acid.

2. The mercury compounds yield saturated ketonic acids after treatment with hydrochloric acids.

3. When mercuric acetate reacts with γ -butinene- α,α -dicarboxylic acid and with γ -butinene- α -carboxylic acid a mixture of mercuric and mercurous salts of indefinite composition results. No ketonic acid has been isolated after treating the mercury compounds with hydrochloric acid.

4. Methyl behenolate gives rise to a crystalline ester of a diacetoxymercuri keto-behenic acid. Hydrochloric acid liberates from this methyl 14-ketobehenate.

ARYLSULFURCHLORIDES AND ARYLSULFURANILIDES

BY E. GEBAUER-FÜLNEGG¹

RECEIVED MAY 17, 1927

PUBLISHED SEPTEMBER 2, 1927

There are two types of arylsulfurchlorides described in the literature: first, substances containing a nitro group in position ortho to the sulfur-chloride radical² and, second, compounds which have no nitro group in the molecule, the ortho and para positions being free or substituted.³

Both types of substances are colored intensely orange-red. But while the arylsulfurchlorides of the first class give highly-colored derivatives, we find the derivatives of the second class (with no substitution of a nitro group) to be colorless. Zincke, who first prepared and studied these substances, has already stated these facts.³ He concluded that the color of the mother substances is due to the sulfur-chlorine linkage, while the color of the derivatives is caused by the nitro group.

Lecher, who prepared the phenylsulfurchloride,⁴ attributes the color of this compound to the loose sulfur-chlorine bond, calling it a new chromophore. He also shows the analogy to SCl_2 .⁵ Neither explanation is entirely satisfactory, as they do not explain the different appearance of the derivatives of the two types of arylsulfurchlorides from a unifying point of view. That the sulfur-chlorine linkage is undoubtedly a loose one is readily apparent from the high reactivity of the compounds and from the investigations of Lecher. Another interesting behavior may be noted. If they are treated in indifferent solvents with hydriodic acid, iodine is immediately liberated; but if they are shaken with silver nitrate or silver carbonate, silver chloride is precipitated even with careful exclusion of moisture. Thus, the arylsulfurchlorides seem to exhibit the properties of chlorine in hydrochloric acid as well as chlorine in sodium hypochlorite. From an electronic conception this dual behavior indicates that these sulfurchlorides, when submitted to the action of different classes of reagents, react as if electromers were present. Experiments on this matter have been carried out with the 4-chloro-2-nitrophenylsulfurchloride.

That this peculiar behavior of the chlorine atom as such in these compounds is not responsible for the color of the arylsulfurchlorides, can be shown by comparison with the analogous aliphatic chloro-amines. Here, too, we find that addition of hydriodic acid is followed by liberation of

¹ International Research Fellow.

² Zincke, *Ann.*, **416**, 86 (1918).

³ Zincke and Eismayer, *Ber.*, **51**, 755 (1918).

⁴ Lecher and Holschneider, *Ber.*, **57**, 755 (1924).

⁵ In this case the suggestion that the behavior of the sulfur-chlorine bonds is the direct cause for the development of color is very probable as no further alteration of the molecule can occur.

iodine but, on the other hand, reactions occur with potassium cyanide.⁶ The chloro-amines are not appreciably colored. Furthermore, this loose sulfur-chlorine linkage itself does not seem to be the essential chromophore, as Lecher has suggested. It seems, rather, to cause an alteration⁷ of the benzoid structure of the molecule and, as a consequence of a shifting of the valences, a quinoid state in the benzene ring is approached. This assumption does not imply that a fixed quinoid structure in the customary sense of the word results from these valence changes.⁸

In order to make this assumption clear, it will be explained and discussed on the example of a definite nitro-substituted arylsulfurchloride and an anilide.

The 4-chloro-2-nitrophenylsulfurchloride (II) is unsaturated. We accordingly find, as already mentioned, a tendency for a quinoid structure initiated by the loose sulfur-chlorine bond. This unsaturated state of the molecule remains the same when the anilide (derivative) is formed, because of the unsaturation of the nitro group itself. Therefore, the approached "quinoid" structure of the derivative of type (III) is possible. An aci form (IV), too, is conceivable. In the formulas the attempt has

been made to indicate this unsaturation of the molecule by means of curved lines, which represent primary valences not yet shifted to the quinoid end-stage. It is difficult to express this conception with the usual symbols for quinones since we associate with them only an end-stage of unsaturation in the molecule.

To decide whether the actual structure of the 4-chloro-2-nitrophenyl-sulfuranilide is that expressed in formula (III) or the aci form (IV), the corresponding methylanilide was prepared. In case that the latter (or any ring formation, where the anilido-nitrogen atom participates) should

⁶ Berg, *Ann. chim. phys.*, [7] 3, 338, 350 (1897).

⁷ For a similar conception, to a certain extent, see Georgievics, "Die Beziehungen zwischen Farbe und Konstitution," Schulthess and Co., Zurich, 1921, pp. 14-15.

⁸ Difficulties encountered in avoiding the formation of higher chlorinated products by some arylsulfurchlorides, Ref. 3, for other references see Ref. 4, seem to indicate the expected higher reactivity of such "quinoid" substances.

prove correct, a distinctly less colored derivative would have been expected but, as a matter of fact, a highly-colored orange solution was obtained, indicating that equilibration of the valence forces occurs in the grouping as expressed in formulas (III) and (IIIa). However, from the point of view of the theory of H. Kaufmann⁹ a ring formation through residual valences as indicated in formula (V), too, could explain the color phenomena encountered; but the assumption of the approached quinoid state seems to simplify the matter, involving no conception of a "Valenzersplitterung" and besides representing better the impression of valence force fields.

Fig. 1.— — = 4-chloro-2-nitrophenylsulfurchloride, 0.000449 *M*; - - - = 4-chloro-2-nitrophenylsulfuranilide, 0.0002018 *M*, in CHCl_3 .

In the molecule of the arylsulfurchlorides not substituted with a nitro group we find the same loose sulfur-chlorine bond, causing a similar shifting of the valence forces in the whole molecule. But by replacing it by the stronger sulfur-nitrogen linkage, shifting back to the benzoid structure occurs, as there is no possibility of maintaining the initial state, as a consequence of the lack of another unsaturated group. From this point of view, the explanation of the fact of the color in the case of the nitro-substituted arylsulfurchlorides and their derivatives has been shown to be as easy as the explanation of the fact that the derivatives of the also highly-colored sulfurchlorides, not substituted with a nitro group, are colorless.

To verify this assumption, Mr. Palmateer of Chicago University was kind enough to take pictures of the absorption spectra of 1, (a) 4-chloro-2-nitrophenylsulfurchloride and (b) 4-chloro-2-nitrophenylsulfuranilide; 2, (c) 4-chlorobenzenesulfurchloride, (d) 2,5-dichlorobenzenesulfurchloride,

⁹ Kaufmann, "Die Auxochrome," Ahrens Vorträge, 1908, 12, 1.

(e) 2,5-dichlorobenzenesulfuranilide. The pictures show that the colored substances (a)-(d) appear to have the same structure, and (a) and (b) check almost exactly. No change in the degree of unsaturation occurred through the formation of the anilide. From that it follows that the cause for the color from (a) and (b) is the same, not as Zincke suggested a different one. That the S-Cl bond as such is not the chromophore can be deduced from the same fact. If this were the case we should expect an altered curve for (b), as the supposed chromophore has been changed chemically.

Furthermore, the similarity of (a) and (c) shows that the nitro group as such has no essential part in the development of the color, but only augments the rise of the curves.

Fig. 2.— $M/1000$ ---- = 4-chlorobenzenesulfurchloride; $M/1000$ — = 2,5-dichlorobenzenesulfurchloride; $M/1000$ - - - = 2,5-dichlorobenzenesulfuranilide in CHCl_3 .

Finally, we see in (e) a new form of the absorption spectrum, indicating an entire change in the structure.

The substances (c) and (d) which were prepared show in their chemical and physical properties a distinct analogy to the phenylsulfurchloride of Lecher, and they have been prepared in the same way. In addition, an anilide of the 4-chloro-2-nitrophenylsulfurchloride was prepared with amino-azobenzene, which is highly red in color. The 4-chloro-2-nitrophenylsulfur radical produced in this case, as expected, a positive color change. It might be possible to utilize this observation in dyestuff chemistry. I hope to present in the future other cases in which an approached quinoid state of organic substances will explain color phenomena.

Experimental Part

The 2,5-dichlorobenzenesulfurchloride was prepared by dropping a solution of 5 g. of well-dried 2,5-dichlorothiophenol into 150 cc. of dry, ice-cold carbon tetrachloride through which was passed a slow current of chlorine. During the reaction the solution, which became yellow, was well stirred. After evaporating the carbon tetrachloride in vacuo the product was obtained by fractionation in a high vacuum. The substance which boiled constantly under 3 mm. at 92° analyzed well for a 2,5-dichlorobenzenesulfurchloride.

Anal. Subs., 0.0971, 0.1511: AgCl, 0.1970, 0.3060; BaSO₄, 0.1080, 0.1667. Calcd. for C₆H₃Cl₂S: Cl, 49.86, S, 15.03. Found: 50.19, 50.10, 15.28, 15.15.

The corresponding anilide was obtained by treating one molecule of the 2,5-dichlorobenzenesulfurchloride with two molecules of redistilled aniline in well-dried chloroform or carbon tetrachloride. After filtration from aniline hydrochloride and evaporation of the filtrate in a vacuum, the residue was crystallized from ligroin. White needles melting at 85° were obtained.

Anal. Subs., 0.1002: N, 4.6 cc. (763 mm., 22°); 0.1294 g., 5.9 cc. (765 mm., 20°). Calcd. for C₁₂H₇Cl₂SN: 5.19. Found: 5.33, 5.35.

The 4-chlorobenzenesulfurchloride was obtained in an analogous way to the 2,5-dichlorobenzenesulfurchloride. Its boiling point under 6 mm. pressure was 94°.

Anal. Subs., 0.1643, 0.1081: AgCl, 0.2650, 0.1740; BaSO₄, 0.2177, 0.1417. Calcd. for C₆H₄Cl₂S: Cl, 39.62; S, 17.92. Found: 39.90, 39.81, 18.20, 18.00.

If one molecule of 4-chloro-2-nitrobenzenesulfurchloride in ether solution is treated with an ethereal solution of amino-azobenzene, reaction occurs. After filtering off the amino-azobenzene hydrochloride which forms, red crystals are obtained by evaporation of the solution. On recrystallization from ether they melt at 188°. The values from the N combustion agree well with the calculated figures for an anilide of 4-chloro-2-nitrophenylsulfurchloride with amino-azobenzene.

Anal. Subs., 0.1424, 0.1167: N, 18.3 cc. (758 mm., 22°), 14.9 cc. (760 mm., 22°). Calcd. for C₁₈H₁₃N₄O₂ClS: N, 14.56. Found: 14.83, 14.77.

2,4-Diamino-azobenzene and 4-chloro-2-nitrobenzenesulfurchloride react apparently in the same way, yielding small brownish-red crystals.

To prepare the 4-chloro-2-nitrophenylsulfurmethylanilide, 2 moles of methylaniline were treated with 1 mole of 4-chloro-2-nitrophenylsulfurchloride in absolute ether solution. After filtration, the deeply-colored solution was evaporated. The resulting orange-red, sirupy mass could not be obtained in a crystalline form, but solidified after several days. No better results have been observed by the use of other solvents such as chloroform and redistilled methylaniline. Further attempts to obtain this product in a crystalline form will be made. The analysis of the solidified material showed the presence of the expected product.

Anal. Subs., 0.1329, 0.1537: N, 11.1 cc. (765 mm., 21°); 12.9 cc. (760 mm., 21°). Calcd. for C₁₄H₁₁N₂SClO₂: N, 9.51. Found: 9.76, 9.58.

The author wishes to express his appreciation to Professor Lauder W. Jones for his assistance in this investigation.

Summary

1. A modified conception of the quinoid theory of colored substances has been offered.

2. Color phenomena in the series of the arylsulfurchlorides and their derivatives have been discussed and explained from this point of view.

3. Absorption spectra of some arylsulfurchlorides and their anilides have been presented and discussed.

4. New arylsulfurchlorides and anilides have been prepared.

ACTION OF THE GRIGNARD REAGENT ON ALKYLBARBITURIC ACIDS

By ARTHUR W. DOX

RECEIVED MAY 18, 1927

PUBLISHED SEPTEMBER 2, 1927

The 5,5-dialkylbarbituric acids, a number of which have come into extensive use as sleep-producing drugs, all contain three carbonyl groups, one or more of which should be expected to react with the Grignard reagent. Although commonly termed "acids," because the unsubstituted parent substance has certain very pronounced acid properties, these derivatives possess more the character of imides. For example, their solubility in alkali is due to a replacement of imide hydrogen by metal. Although two such imide groups are present only one is thus replaceable.

According to Béis¹ the more familiar types of imides, such as phthalimide, react with the Grignard reagent, but here only one of the two carbonyls is affected. With Grignard reagent prepared from normal alkyl halides, Béis noted a dehydration of the initial reaction product. This is attributed to a splitting out of water between the hydroxyl on the nucleus and a hydrogen of the side chain. The product obtained from phthalimide and ethyl magnesium bromide would be, therefore, not an ethyl-*iso*-indolone (Formula I) but rather an ethylidene phthalimidine (Formula II). The phenyl group, on the other hand, cannot give up a hydrogen in this manner and dehydration does not occur, the product with phenyl magnesium bromide being a phenylhydroxy-*iso*-indolinone. However, Sachs and Ludwig² obtained from *N*-ethylphthalimide and ethyl magnesium bromide a product analogous to Béis' phenyl Grignard product. In other words, with imide hydrogen already replaced by alkyl the dehydration

¹ Béis, *Compt. rend.*, **138**, 987; **139**, 61 (1904).

² Sachs and Ludwig, *Ber.*, **37**, 388 (1904).

did not occur. The location of the double bond resulting from dehydration is still in question, leaving a choice between Formulas I and II.

With dialkylbarbituric acids and the Grignard reagent two carbonyls react, but in the dehydration which also occurs only one molecule of water is removed. Moreover, phenyl magnesium bromide gives the same type of product as do the alkyl magnesium bromides; and, further, a tetra-alkylbarbituric acid with no replaceable hydrogens gave a reaction between all three carbonyls and the Grignard reagent, but only one molecule of water was split out. The dehydration in the case of alkylbarbituric acid reaction products must, therefore, occur in a manner different from that represented in either Formula I or II.

Experimental

In all of the preparations described herein an excess of the Grignard reagent was used. To this was slowly added, with continuous stirring, an ethereal solution of the alkylbarbituric acid. Each drop gave momentarily a white precipitate, possibly a magnesium salt of the barbituric acid, which immediately dissolved again. After all had been added the mixture was refluxed for one and a half to two hours, and then treated in the usual way with dilute sulfuric acid. Products containing smaller alkyl groups had a tendency to crystallize out of the ether layer; those of higher molecular weight usually remained in solution and were obtained crystalline by evaporation of the solvent. Recrystallization from alcohol gave fine, slender needles. None of the products melted at 250° , and those with lower molecular weight sublimed without melting and apparently without decomposition.

Analysis of the product obtained from diethylbarbituric acid and ethyl magnesium bromide showed that two carbonyls had reacted and that one molecule of water had been split out. The calculated empirical formula is $C_{12}H_{22}O_2N_2$, which may be represented by either of two structures, III or IV.

For reasons to be discussed presently, Formula IV appears the more probable of the two. The substance will, therefore, be designated, pro-

visionally, endo ether of 4,6-dihydroxy-4,5,6-tetra-ethyl-2-ketohexahydropyrimidine. It is insoluble in water and benzene, moderately soluble in alcohol, but unlike diethylbarbituric acid it is insoluble in sodium hydroxide. Removal of any traces of unreacted dialkylbarbituric acid is easily effected by extraction with dilute alkali. The substance dissolves readily in concentrated sulfuric, hydrochloric and acetic acids, and is precipitated unchanged from these solutions by dilution with water.

Anal. Subs. 0.1446, 0.1577: CO_2 , 0.3394; H_2O , 0.1304; N_2 , 18.2 cc. (738 mm., 28°). Calcd. for $\text{C}_{12}\text{H}_{22}\text{O}_2\text{N}_2$: C, 63.72; H, 9.73; N, 12.39. Found: 64.01, 10.02, 12.29.

The substance is surprisingly resistant to hydrolysis. When the solution in concentrated hydrochloric acid is gently refluxed, the original substance separates out again as soon as the loss by evaporation diminishes the concentration of acid to the constant-boiling solution. After two hours' refluxing 94% of the original material was recovered unchanged. Six hours' heating in a sealed tube at 160–180° with ten parts of 25% sulfuric acid was insufficient to effect hydrolysis; 89% of the substance was recovered unchanged. Three hours' refluxing of 1 g. with 1 g. of potassium hydroxide in 50 cc. of alcohol likewise failed to effect hydrolysis, the recovery in this case being 89%. Hydrolysis was accomplished, however, by heating for seven hours at 150–160° in a sealed tube with ten parts of concentrated hydrochloric acid, and also by seven hours' heating in an oil-bath at 130–135° with 50% by volume sulfuric acid. The products obtained were ammonium chloride and sulfate, respectively, and a volatile oil with characteristic ketone odor. The oil, after purification by steam distillation, was soluble in water and reacted with hydroxylamine and with phenylhydrazine, forming liquid products which failed to crystallize in a freezing mixture. The initial products of hydrolysis should be a diketone of the formula $(\text{C}_2\text{H}_5)_2\text{C}(\text{COC}_2\text{H}_5)_2$ and urea. These probably undergo further hydrolysis to form diethylketone and ammonia.

In a similar manner other dialkylbarbituric acids reacted with various alkyl magnesium halides, giving products of much the same properties. In all cases the nitrogen content agreed with that calculated for products of the same type, that is, alkylation of two carbonyls and loss of one molecule of water.

DIALKYLBARBITURIC ACIDS + RMgBr

Barbituric acid	Grignard	Product	N	
			Calcd.	Found
Diethyl	Ethyl	$\text{C}_{12}\text{H}_{22}\text{O}_2\text{N}_2$	12.39	12.29
Ethylphenyl	Ethyl	$\text{C}_{16}\text{H}_{22}\text{O}_2\text{N}_2$	10.22	9.98
Ethyl- <i>iso</i> -amyl	Ethyl	$\text{C}_{16}\text{H}_{28}\text{O}_2\text{N}_2$	10.11	10.16
Diethyl	Phenyl	$\text{C}_{20}\text{H}_{22}\text{O}_2\text{N}_2$	8.70	8.62
Diethyl	Propyl	$\text{C}_{14}\text{H}_{26}\text{O}_2\text{N}_2$	11.02	11.05
Diethyl	<i>n</i> -Butyl	$\text{C}_{18}\text{H}_{30}\text{O}_2\text{N}_2$	9.93	10.18

Diallyl	<i>iso</i> -Amyl	$\text{C}_{20}\text{H}_{34}\text{O}_2\text{N}_2$	8.38	8.37

The choice between Formulas III and IV could not be determined satisfactorily by hydrolysis whereby a ketone, probably diethylketone, was obtained. If the dehydration occurs between the tertiary alcohol grouping and the adjacent NH, it seems unlikely that only one molecule of water should be split out rather than two. On the other hand, the internal ether structure represented by Formula IV, which contains no double linkage, gives a symmetrical structure for which the observed stability and resistance to hydrolysis might be predicted.

If a similar dehydration takes place when a tetra-alkylbarbituric acid reacts with the Grignard reagent, the only manner in which it could occur would be by formation of an inner ether, since both nitrogens are substituted and no replaceable hydrogen is present. As will be shown directly, this is apparently what takes place.

5,5-Dipropyl-1,3-diphenylbarbituric acid was prepared by dissolving molecular proportions of dipropylmalonic acid and carbanilide in anhydrous chloroform, adding two molecules of freshly distilled phosphorus oxychloride and heating the mixture in an oil-bath for four hours at 65–70°. The chloroform was then evaporated and the residue dissolved in water. Extraction with ether took up the condensation product, along with some dipropylmalonyl chloride, and precipitated out the unreacted carbanilide. Evaporation of the ether left a sirup which could not be crystallized. It was then purified by vacuum distillation. The portion distilling between 150 and 190° at 4 mm. solidified in the receiver, and after washing with petroleum ether and recrystallizing from benzene, it was obtained in white prisms melting at 104–105°. Unlike the di- and trialkylbarbituric acids, which contain replaceable hydrogen, this substance is insoluble in alkali. The yield was small (30%), owing probably to insufficient time of reaction.

Anal. Subs. 0.2254: N₂, 14.9 cc. (749 mm., 23°). Calcd. for C₂₂H₂₄O₂N₂: N, 7.69. Found: 7.35.

The above product was treated in the usual manner with ethyl magnesium bromide. No transient precipitate of a magnesium salt was formed during the reaction. The product after recrystallization from benzene consisted of white needles melting at 102°. A mixed melting point with the tetra-alkylbarbituric acid gave a depression of 8°.

Anal. Subs., 0.1979, 0.1992: CO₂, 0.5607; H₂O, 0.1664; N₂, 11.4 cc. (745 mm., 26°). Calcd. for C₂₈H₄₀O₂N₂: C, 77.06; H, 9.17; N, 6.42. Found: 77.27, 9.34, 6.35.

The empirical formula represents an endo ether of 1,3-diphenyl-2,4,6-triethyl-5,5-dipropyl-2,4,6-trihydroxyhexahydropyrimidine:

The analysis is not in agreement with values calculated for products that would result from the reaction of two carbonyl groups, with or without dehydration. Substitution of both NH groups in the barbituric acid evidently modifies the properties of the third carbonyl in such a way as to render it capable of reacting with the Grignard reagent.

Summary

The reaction between 5,5-dialkylbarbituric acids and the Grignard

reagent consists in the alkylation of two carbonyls and the loss of one molecule of water, probably with formation of an internal ether. With a tetra-alkylbarbituric acid the same reaction occurs, also an additional reaction of the third carbonyl.

**THE STRUCTURE OF THE CONDENSATION PRODUCTS OF
 ORTHO-PHTHALALDEHYDIC ACIDS WITH PHENOLS AND
 PHENOL ETHERS. VIII.¹**

BY M. M. BRUBAKER² WITH ROGER ADAMS

RECEIVED MAY 23, 1927

PUBLISHED SEPTEMBER 2, 1927

The preparation of substituted phthalides from *ortho*-phthalaldehydic acid by condensation with phenols was discovered by Bistrzycki.³ He found that the phthalides formed could be reduced to benzyl-benzoic acids and these in turn could be dehydrated and the anthrones oxidized to anthraquinones.

This procedure for preparing certain types of anthraquinones appeared, at first, not to be entirely general, since he was unable to reduce phthalides from opianic acid (2-carboxy-3,4-dimethoxybenzaldehyde) and phenols to the corresponding benzyl-benzoic acids. Jacobson and Adams,^{1d} however, found that under the proper conditions these latter phthalides could be reduced, and, although the benzyl-benzoic acids could not in all cases be obtained crystalline and pure, the products served well for the preparation of anthraquinones. In this Laboratory the method has already been applied to the synthesis of morindone,^{1e} rufiopin^{1g} and

hydroxyanthrarufin. With a certainty of the reduction of the phthalides, the value of this procedure as a means of preparing hydroxyanthraquinones of various known structures depends upon a definite knowledge of the structure of the phthalide. Bistrzycki prepared beta-hydroxyanthraquinone by the series of reactions given above and thus demonstrated without question the structure of the intermediate phthalide; the condensation of the *o*-phthalaldehydic acid takes place *para* to the hydroxyl group of the phenol. He therefore assumed that when opianic acid was used in place of the unsubstituted *o*-phthalaldehydic acid, the condensation with phenol or substituted phenols always proceeded *para* to the hydroxyl. In a series of researches from this Laboratory,^{1e,1f,1g} the condensation was directed *ortho* to the hydroxyl group by starting with a *p*-halogenated phenol and the halogen was later removed during reduction to the benzyl-benzoic acid. From time to time in the course of these investigations, it appeared doubtful whether the condensation of opianic acid and phenols with both *ortho* and *para* positions unoccupied always went *para* to the hydroxyl group. Since the success of several problems depended upon a knowledge of this fact, a study was undertaken to determine the structure of the phthalides formed, in other words, the exact position assumed in the condensation of opianic acid with phenols and certain substituted phenols. This paper describes also the results of the condensation of opianic acid with phenol ethers, a continuation of the study of the condensation of *o*-phthalaldehydic acid with certain phenols, the condensation of bromo-opianic acid with phenol, and finally a new class of compounds, the *bis*-phthalidyl phenols or phenol ethers where two molecules of the *o*-phthalaldehydic acid condense with one of phenol or phenol ether.

Bistrzycki^{3a,b} condensed opianic acid with phenol and obtained what he considered to be the *para* condensation product (I), though it was obviously impure on account of the melting point reported (160–170° with previous softening).

He was unable to reduce this compound to the corresponding benzyl-benzoic acid. A repetition of this reaction was carried out, and, by a different method of crystallization of the crude product, a pure compound was isolated which melted sharply about 20° higher than the m. p. reported by Bistrzycki. This product was shown without question to be that in which the condensation had taken place in the *ortho* position to the hydroxyl, (II), because on bromination the same monobromo compound (III) resulted as was formed by the condensation of opianic acid with *p*-bromo-

phenol. Moreover, upon reduction of the phthalide, the same benzylbenzoic acid was produced as that formed by the reduction of the phthalide from opianic acid and *p*-bromophenol (III).

This demonstrated that the *ortho* condensation product (II) was formed to a large extent, contrary to what might be expected from Bistrzycki's work with *o*-phthalaldehydic acid. The presence of the *para* condensation product (I) was also demonstrated. It may be stated here that one of the outstanding characteristics of the condensation products from opianic acid and many of the phenols is the slow rate of crystallization. In some instances several days are required for complete crystallization even in the presence of a seed. This is particularly true if isomeric impurities are present and separations by crystallization are frequently rendered difficult, due to the formation of gums. It was discovered early in this work that the bromine derivatives could, in all cases, be crystallized much more readily, and mixtures of these bromo compounds could frequently be separated with comparative ease. Opianic acid was, therefore, condensed with phenol and the crude reaction product brominated in glacial acetic acid. A monobromo compound was readily isolated and purified. If, before bromination, both *ortho* and *para* condensation products were present, there are three possible structures for the brominated compound, (III), (V) and (VI), assuming that the bromine enters only the phenol nucleus.

The structure of the compound was shown to be that represented by (VI), namely, the monobromo derivative of the phthalide in which the opianic acid was condensed *para* (I) to the hydroxyl group of the phenol. This was demonstrated first by condensation of opianic acid with *o*-bromophenol, which gave the same substance (VI) in excellent yields, thus restricting the structure to (VI) or (V) and eliminating the possibility of bromination in the opianic acid ring. Upon reduction of the bromine compound (VI) a benzyl-benzoic acid resulted which was not identical with the benzyl-benzoic acid formed by reducing either the phthalide isolated from the reaction of opianic acid and phenol or the phthalide from opianic acid and *p*-bromophenol. Since the latter benzyl-benzoic acid must have the linkage *ortho* to the hydroxyl group, the new benzyl-benzoic acid must have the linkage *para*, and formula (V) is thus eliminated. The presence of both *ortho* and *para* compounds in the condensation of opianic acid with phenol is thus substantiated.

A similar plan of attack for the determination of the structure of the opianic acid and *o*-cresol compounds was followed. The probability is that a mixture of isomers, (VII) and (VIII), is also produced here.

Bistrzycki^{3c} isolated a substance which he was unable to reduce to the corresponding benzyl-benzoic acid. Jacobson and Adams repeated the

work and obtained apparently the same phthalide, but it melted several degrees higher than reported by Bistrzycki. A successful reduction of the compound to a benzyl-benzoic acid was carried out, though the latter was never obtained in a crystalline state. The phthalide, after isolation in essentially a pure state from the reaction mixture, was brominated and a monobromo product readily produced (IX). This was shown to be identical with the condensation product of opianic acid and *o*-bromo-*o*-cresol, demonstrating that the original reaction must have taken place *para* to the hydroxyl group. The reduction of this brominated product yielded a crystalline benzyl-benzoic acid (X). It is thus obvious that the benzyl-benzoic acids, like the phthalides, readily form gums unless the products are absolutely pure. Since the brominated phthalides are easily purified, it is desirable to use these substances as intermediates if a pure benzyl-benzoic acid is to be readily obtained. When opianic acid is condensed with *p*-bromo-*o*-cresol, the condensation undoubtedly goes *ortho* to the hydroxyl (XI). This was proved with certainty, because upon reduction a benzyl-benzoic acid results (XII) which is different from the one formed from the bromination of the phthalide from opianic acid and *o*-cresol. The isolation of the isomer was not attempted.

From the results with the phenol and *o*-cresol condensations, it is obvious that if the *ortho* and *para* positions to the hydroxyl of the phenol are open both isomeric forms are produced, and the pure compound isolated may be either, depending upon conditions used. An *ortho* condensation will take place if the *para* position to the hydroxyl group is occupied, and a *para* condensation if both the *ortho* positions to the hydroxyl are occupied. If only one position *ortho* to the hydroxyl is filled, probably the chief condensation will take place *para* to the hydroxyl. In the condensations with *o*-bromophenol and *o*-bromo-anisole, the yield of *para* condensation products was practically quantitative. With the *o*-cresol this was not true, and ordinarily it would be necessary to determine the structure of the product with certainty where the compound was to be used as an intermediate for structural work. The same conclusion in regard to orientation may be drawn about the phenol ethers which are described below.

Two products were isolated when opianic acid was condensed with *p*-bromo-*m*-cresol.¹⁸ Since three isomers are possible from the condensation of opianic acid and *m*-cresol, this reaction was not studied.

In many of the condensations of opianic acid with phenol and phenol derivatives, high-melting by-products were formed in small quantities. Analyses of these compounds revealed the fact that they were not simple phthalides, isomeric with the normal products, but *bis*-phthalidyl compounds formed from two molecules of opianic acid and one molecule of the phenol or phenol derivative. Experiments showed that the amount

of by-product formed could be increased from small quantities to good yields by using two molecular proportions of opianic acid to one of the phenol or phenol derivative, and also by increasing the strength of the sulfuric acid used in condensation.

There are two possible structures for these compounds, one in which two molecules of opianic acid condense in the phenol ring, probably in the positions *ortho* and *para* to the hydroxyl (XIII), and the other in which an opianic acid molecule condenses in the opianic nucleus of the primary product (XIV).

Since the vacant positions in opianic acid are rather difficult to substitute, such a condensation as that represented by formula (XIV) would appear unlikely.

The structure of the *bis*-phthalidyl compound in the case of opianic acid and *o*-cresol was shown definitely to be (XV). If either the *ortho* or *para* position to the hydroxyl in the *o*-cresol nucleus is not occupied, bromination might be expected to take place readily in the cold, similar to the quantitative bromination in the cold of many analogous compounds, (see formulas VIII and IX). The *bis*-phthalidyl *o*-cresol derivative, however, could not be brominated at all in the cold. Upon heating with bromine in glacial acetic acid for two hours, two bromine atoms are introduced. The compound resulting from this bromination (XVI) was found to be identical with the *bis*-phthalidyl compound formed from bromo-opianic acid and *o*-cresol, showing that in the original bromination a bromine atom was introduced into each of the opianic acid nuclei.

This establishes the fact beyond a doubt that the *o*-cresol ring is substituted in two positions and eliminates the possibility of formula (XIV).

The *bis*-phthalidyl compound from opianic acid and phenol has an *ortho* position to the hydroxyl in the phenol nucleus unfilled (XIII). Bromination might then be expected to take place in the cold with the entrance of a single bromine atom into the phenol nucleus. This actually

occurs and a compound (XVII) was produced, identical with the *bis*-phthalidyl compound obtained from the condensation of opianic acid and *o*-bromophenol.

The above experiment also indicates that two opianic acid nuclei have condensed with phenol in the positions *ortho* and *para* to the hydroxyl, rather than in the two *ortho* positions. Methylation of the *bis*-phthalidyl compound from opianic acid and phenol gives a compound identical with the *bis*-phthalidyl derivative from opianic acid and anisole, so its structure may be represented by formula (XVIII).

Early experiments by Bistrzycki^{3a} indicated that *o*-phthalaldehydic acid could not be condensed with phenol ethers, for no product was obtained from *o*-phthalaldehydic acid and phenetole. He was able later,^{3c} however, to condense opianic acid and *o*-phthalaldehydic acid, with both *o*-cresol methyl ether and veratrole. It has been shown in this investigation that the condensation of opianic acid and *o*-phthalaldehydic acid with phenol ethers is as general a reaction as that with phenols; *o*-phthalaldehydic acid has been condensed with anisole and *p*-bromo-anisole, and opianic acid has been condensed with anisole, *p*-bromo-anisole, *o*-bromo-anisole and *p*-bromo-*m*-cresol methyl ether.

It is very difficult to obtain a pure phthalide from opianic acid and anisole. Considerable *bis*-phthalidyl compound from the condensation of two molecules of opianic acid and one of anisole (XVIII) is formed, due probably to the fact that the anisole is not as soluble as the opianic acid in the 73% sulfuric acid used as a condensing agent, with the result that there is an excess of the opianic acid always present in solution. The gum from the condensation has been shown to contain both isomeric phthalides (XIX) and (XX). By very slow and tedious crystallization, small amounts of the *para* isomer (XX) may be isolated. That the compound was the *para* isomer was concluded from the fact that it was not identical with

the *ortho* isomer prepared by the methylation of the *ortho* hydroxyl compound (II), the determination of the structure of which was described earlier in the paper. If the crude product is brominated directly, a bromo derivative (XXI) can be separated, identical with the condensation product of opianic acid and *p*-bromo-anisole, thus indicating that a portion of the condensation product is the *ortho* isomer (XIX).

In contrast to the mixture of isomers and the poor yield which is obtained in the condensation of opianic acid with anisole, a quantitative yield of a pure product is obtained with *o*-bromo-anisole, the structure of which has been shown to be (XXII), for it is identical with the compound obtained by methylation of the phthalide from opianic acid and *o*-bromophenol (VI) and the structure of the latter has already been established.

As in the condensation with phenol so with anisole, the simple *o*-phthalaldehydic acid gives more readily crystallizable products, and a fair yield of the *para* isomer with anisole may be isolated. *o*-Phthalaldehydic acid also condenses with *p*-bromo-anisole to give a product which has, undoubtedly, the structure (XXIII).

bis-Phthalidyl compounds from *o*-phthalaldehydic acid were not isolated as by-products in forming the phthalides, and an attempt has not yet been made to modify conditions so as to obtain them.

In determining the structure of the pure phthalides isolated from the condensations of opianic acid with phenol, anisole, *o*-cresol and *m*-cresol, an attempt was made to produce the pure *ortho* phthalides for comparison by catalytic reduction of the halogen from the halogenated phthalides formed by the condensation of opianic acid and *p*-bromophenols. Blocking the position *para* to the hydroxyl directs the condensation to the *ortho* position. Consequently, as, for example, in the case of the phthalide from opianic acid and *p*-bromo-*o*-cresol, if the removal of the halogen from this phthalide (XI) could be effected, a compound would result which would be the phthalide from opianic acid and *o*-cresol, provided the condensation had taken place in the *ortho* position.

Catalytic reduction with platinum-oxide platinum black was not satisfactory for this reaction because after the halogen was replaced by hydrogen in part of the material, further reduction took place in the product before all of the original bromine compound was reduced. This is due, in part at least, to the fact that the bromine compounds used are not very soluble in the alcohol employed as a solvent and have to be reduced in partial suspension. It was not possible in any instance to stop the reduction at the desired point. From two to five moles of hydrogen were usually absorbed before all of the original material was in solution and the products consisted of a mixture of sodium carbonate soluble compounds from which the halogen-free benzyl-benzoic acids were isolated in several experiments in yields varying from a trace to 57% of the calculated amount.

The phthalides from opianic acid with *p*-bromo-*o*-cresol, *p*-bromo-*m*-cresol (condensation *ortho* to the methyl group) and *o*-bromophenol, and from *o*-phthalaldehydic acid with *p*-bromo-anisole, were reduced in this manner and the pure, halogen-free benzyl-benzoic acids isolated. The phthalides from opianic acid with *p*-bromo-*m*-cresol (condensation *para* to the methyl group) and *p*-bromophenol were reduced but only gums isolated. Undoubtedly hydrogenation of the aromatic nuclei also took place to a certain extent in most of the reduction experiments.

Experimental

General Method of Preparation of Phthalides.—The phthalides were prepared by mixing equimolar proportions of opianic acid (or *o*-phthalaldehydic acid) and phenol or phenol ether with sulfuric acid in the proper strength (as given in the table), in the

proportion of 50 cc. of sulfuric acid to 0.1 mole of the phthalaldehydic acid. The sulfuric acid was previously cooled in an ice-salt bath to 0° to prevent the reaction from overheating. External cooling was applied if the temperature of the reaction rose above 25–30°, as a higher temperature led to the deepening of the color of the reaction product and to the formation of a certain amount of by-product.

The reactions were probably complete within an hour but were allowed to stand at room temperature overnight. Ice and water were then added to the reaction mixtures, causing the products to separate either as solids or as gums, as, for example, when phenol, anisole, *m*-cresol or *o*-cresol were used. The crude material was then washed with water.

In the condensation of opianic acid with phenol, anisole, *o*-cresol or *m*-cresol, the opianic acid is added in small portions to a mechanically stirred mixture of the phenol or phenol derivative and the condensing acid. This procedure reduces to a minimum the amount of the by-product formed from two molecules of opianic acid and one of phenol or phenol ether. Because of the slight solubility in the condensing acid this order of mixing is particularly desirable in the case of phenol ethers, so that an excess of opianic acid will never be present to make possible the formation of more by-product.

The phthalides from *p*-bromophenol, *p*-bromo-*o*-cresol, *p*-bromo-*m*-cresol, *o*-bromophenol, *p*-bromo-anisole, *o*-bromo-anisole, *o*-bromo-*o*-cresol, *p*-bromo-*m*-cresol methyl ether with opianic acid and from phenol, anisole and *p*-bromo-anisole with *o*-phthalaldehydic acid were very conveniently prepared by adding the condensing acid to an intimate mixture of the phthalaldehydic acid and phenol, or phenol ether, since the formation of by-products was ordinarily not observed if molecular proportions were used. The reaction mixtures often solidified to a hard cake, which prevented mechanical stirring and made it desirable to use as a reaction vessel an evaporating dish and as a stirrer, a pestle. The reaction products were poured into ice and water and then thoroughly washed.

The very small amounts of by-products formed in the phenol and *m*-cresol condensations were eliminated by four or five crystallizations of the crude product from acetic acid. In the anisole and *o*-cresol condensations, the separation of the by-product was more difficult. The by-products are only slightly soluble in hot alcohol, so that the gummy condensation mixtures were dissolved in this solvent. The solid by-product generally separated directly, particularly if the hot solution was allowed to cool in the presence of seed. Even by this procedure it was impossible to obtain a pure *o*-cresol condensation product, due, probably, to the retention of small amounts of by-product.

The crude reaction products are usually very soluble in most organic solvents, whereas after they are once obtained crystalline they are much less soluble. Crystallization of material from solutions of the crude products was almost invariably slow.

Wherever difficulty was encountered in isolation of the pure products, the details for the procedure used are given below. In the table is a list of the most convenient proportions of solvent for crystallization of relatively pure product, and the recovery is almost always 80–90%. The yields referred to in the tables are also of crystalline material, and this is important because practically quantitative yields of crude product are always obtained. The melting points in all cases are corrected.

5,6-Dimethoxy-2-(2-hydroxyphenyl) Phthalide. II.—The reaction product from 21 g. of opianic acid and 9.8 g. of phenol was thoroughly washed and the gum dried. It was dissolved in 125 cc. of hot glacial acetic acid in the presence of a little Norit and then filtered. Upon standing, crystals were slowly deposited, and crystallization was complete in the course of a day or two. The presence of seed assures a more rapid initial crystallization, but for completion essentially the same time is required as mentioned above. In this way 8.2 g. (29%) of crystalline material was obtained. Another small deposit may be obtained from the filtrate but beyond this, evaporation or cooling yields

no more crystals. The compound is purified from acetic acid (1 g. in 6 cc.) and forms triangular plates; m. p., 177-178°.

^a Resolidifies and melts at 141°.

^b Resolidifies and melts at 178-9°.

^c Ref. 1 f.

5,6-Dimethoxy-2-(2-methoxyphenyl) Phthalide. XIX.—A solution of 2.5 g. of 5,6-dimethoxy-2-(2-hydroxyphenyl) phthalide in 4 cc. of 10% sodium hydroxide solution was diluted with 25 cc. of water and shaken with 2 cc. of dimethyl sulfate. The

solution was filtered, acidified and the resulting gum dried and washed. Crystallization from dilute alcohol gave 0.75 g. of solid material. This was crystallized by dissolving in a hot mixture of 10 per cent. absolute alcohol in petroleum ether (70–80°). As the solution cooled, a gum separated which was made just to redissolve by addition of a sufficient amount of absolute alcohol. The resulting solution was allowed to stand for two days and large crystals slowly formed. These were filtered and washed with 10% absolute alcohol in petroleum ether. They melted at 102–103°.

A mixture of this substance with 5,6-dimethoxy-2-(4-methoxyphenyl) phthalide, prepared by the condensation of anisole and opianic acid, showed a melting point of 60–70°, thus indicating that they were not identical.

Bromination in glacial acetic acid gave 5,6-dimethoxy-2-(2-methoxy-5-bromophenyl) phthalide, identical with the compound described later that was produced by condensing opianic acid with *p*-bromo-anisole.

5,6-Dimethoxy-2-(4-methoxyphenyl) Phthalide. XX.—The gummy reaction product from 0.05 mole of opianic acid and anisole was dissolved in about 50 cc. of hot alcohol and cooled. Practically all of the by-product present separated and was filtered. The filtrate was evaporated, and the resulting gum washed with 5% sodium carbonate solution, and then treated with a small amount of ether. In this way 2 g. (13%) of a fairly pure product crystallized. The only procedure found for purification was to dissolve in hot petroleum ether (90–110°), and to allow this solution to cool very slowly in the presence of a seed. A crystalline deposit which formed in the course of a day or longer was filtered and recrystallized from *n*-butyl ether, thus giving microscopic crystals melting at 93–95°.

5,6-Dimethoxy-2-(2-hydroxy-5-bromophenyl) Phthalide. III.—A well-stirred solution of 2.77 g. of 5,6-dimethoxy-2-(2-hydroxyphenyl) phthalide in 50 cc. of glacial acetic acid was treated with 2.5 cc. of a molar solution of bromine in acetic acid. Evaporation of the solution gave a quantitative yield of a monobromo derivative which was identical with the material obtained by condensation of opianic acid with *p*-bromophenol.¹⁴

5,6-Dimethoxy-2-(4-hydroxy-3-bromophenyl) Phthalide. VI.—The gummy reaction mixture from 10.5 g. of opianic acid and 4.7 g. of phenol was, without purification, dissolved in chloroform and the solution dried. The cooled solution was then mechanically stirred and 60 cc. of a solution of bromine in chloroform was slowly added. Evaporation of the solvent gave a product which was purified by two crystallizations from alcohol followed by four crystallizations from glacial acetic acid. It was then pure, and melted at 207–208°; it proved to be identical with the compound formed by condensation of opianic acid and *o*-bromophenol.

5,6-Dimethoxy-2-(4-methoxy-3-bromophenyl) Phthalide. XXII.—The crude condensation product from 21 g. of opianic acid and 18.7 g. of *o*-bromo-anisole was diluted with 250 cc. of alcohol and cooled without filtering. The resulting crystalline material was filtered and purified by recrystallization from alcohol (1 g. to 30 cc. of alcohol). The product was obtained in practically quantitative yields and melts at 136.5–137°. It resolidified and melted at 141°. If the temperature of the melting-point bath was raised very slowly, crystallization started again before the first melting was complete, so that the compound appeared to soften at 136.5° and to melt at 141°.

Methylation of 5,6-dimethoxy-2-(4-hydroxy-3-bromophenyl) phthalide with dimethyl sulfate and sodium hydroxide gave this same compound and it showed the same phenomenon of melting and resolidification.

***o*-Bromo-*o*-cresol.**—To 108 g. of *o*-cresol, 154 g. (85 cc.) of 95% sulfuric acid was slowly added with cooling. The solution was heated on a steam cone for 8 hours and then poured onto 300 g. of ice in a 2-liter beaker. To the cold reaction solution, 200 g. of powdered barium carbonate was added, in small portions to prevent excessive

foaming. The excess of barium carbonate and the barium sulfate formed were filtered on a large filter and the colored filtrate containing the barium salt of *o*-cresol-*p*-sulfonic acid was brominated. The barium salt of *o*-bromo-*o*-cresol-*p*-sulfonic acid is so insoluble that it separated and formed in such bulk as to prevent thorough agitation. It was found best, therefore, to brominate one-fourth of the filtrate at a time. Such a portion was diluted to 600 cc., treated with Norit, filtered and 12.5 g. of bromine in 15 cc. of acetic acid was slowly added to the well-stirred solution. External cooling was applied to prevent the temperature from rising above 20°. Even in this dilution the copious separation of the product made very efficient stirring necessary and the last half of the bromine had to be added slowly. The precipitate was filtered in some runs when half of the bromine had been added and the bromination was completed in the filtrate. The barium salt which separated was sucked as dry as possible and then triturated with 200 cc. of alcohol for each 0.25 mole portion. The insoluble salt was filtered, washed with two more portions of 50 cc. of alcohol and dried. The acid filtrate from the bromination retained some material because of the solvent action of the hydrobromic acid. This was recovered by adding 50 g. of barium chloride and allowing it to stand for a day. This precipitate was washed with alcohol, dried and added to the main portion. In this way 68.0–72.6 g. (81–87%) of dry barium salt was obtained.

A mixture of 115 g. of the barium salt with a solution of 344 cc. of 95% sulfuric acid in 400 cc. of water was heated to boiling, and live steam passed through. The *o*-bromo-*o*-cresol distilled and was separated from the aqueous solution with carbon tetrachloride. The fraction boiling at 210–220° at 745 mm. and weighing 38 g. (60%) was redistilled under reduced pressure, boiling at 71–73° (7 mm.).

The *o*-bromo-*o*-cresol has previously been prepared by the decarboxylation of 3-methyl-4-hydroxy-5-bromo-benzoic acid.⁴ It is, however, a very unsatisfactory procedure. An attempt was also made to sulfonate *o*-cresol and brominate the diluted acid solution directly. The difficulty in this procedure, however, consisted in the formation of a certain amount of bromine by the oxidation of the hydrobromic acid by the sulfuric acid. The bromine produced then replaced the sulfonic acid group and the resulting product was, for the most part, dibromo-*o*-cresol. By the isolation of the barium salt of the *o*-bromo-*o*-cresol-*p*-sulfonic acid, no such complication was encountered and a good yield of product resulted.

5,6-Dimethoxy-2-(3-methyl-4-hydroxy-5-bromophenyl) Phthalide. IX.—The crude reaction product from 0.05 mole of opianic acid and *o*-bromo-*o*-cresol was washed with water, then with 100 cc. of cold alcohol and filtered. It was crystallized from 125 cc. of alcohol, giving 13.4 g. of crystalline material. A second crystallization from alcohol gave a pure product, melting at 163–164°, which resolidifies and melts again at 178–179°.

Bromination of the phthalide produced by Jacobson and Adams^{1f} from opianic acid and *o*-cresol gives a compound identical with that prepared above.

5,6-Dimethoxy-2-(4-hydroxy-4-methylphenyl) Phthalide.—The crude material from 0.05 mole of opianic acid and *m*-cresol, using 73% sulfuric acid, was dissolved in 50 cc. of glacial acetic acid and allowed to stand for a week. From the viscous solution crystals slowly deposited, which amounted to 2.1 g. when filtered. These were crystallized once from 25 cc. of acetic acid, giving 1 g. of product, and this was further purified by several crystallizations from a constant-boiling mixture of acetic acid and toluene (28% acetic acid). The pure product melts at 191.5–192.5°.

The structure assigned to this compound was merely assumed.

5,6-Dimethoxy-2-(2-methoxy-5-bromophenyl) Phthalide. XXI.—The crude material from 0.05 mole of condensation product of opianic acid and anisole was dissolved in

⁴ Robertson, *J. Chem. Soc.*, 93, 788 (1908).

50 cc. of chloroform and brominated with 45 cc. of a molar solution of bromine in chloroform. The chloroform was evaporated and the gummy reaction product dissolved in 80 cc. of glacial acetic acid. After standing for a day, 3.1 g. (26%) of crystals deposited, which, when purified by recrystallization from acetic acid, melted at 157–158°.

This compound was identical with that obtained by the bromination of 5,6-dimethoxy-2-(2-methoxyphenyl) phthalide in glacial acetic acid or by the condensation of opianic acid with *p*-bromo-anisole.

bis-(Dimethoxyphthalidyl) Phenols and Phenol Ethers

It was mentioned that in the preparation of phthalides from phenol, anisole, *o*-cresol and *m*-cresol, by-products were obtained in small amounts. These by-products, upon further study, proved to be *bis*-phthalidyl derivatives, and could be made practically the main product of reaction in many cases by modification of the amounts of reacting compound and of the conditions. In particular, the concentration of sulfuric acid for condensing was increased and the proportion of opianic acid to phenol or phenol ethers was doubled.

General Method for Preparation of *bis*-Phthalidyl Compounds.—To a mixture of 0.1 mole of opianic acid in 80 cc. of 95% sulfuric acid was added 0.05 mole of phenol or phenol ether, not allowing the temperature to rise above 30°. In the course of three or four hours the reaction mixture was poured into water and the precipitate filtered. The compounds were purified by crystallization from the solvent indicated in the table. The yields ranged from 25–97% and the products were readily purified because of the fact that the mono-phthalidyl compounds were much more soluble in the solvents used.

TABLE II

^a Resolidifies and melts again at about 224°.

2,4-bis-(5,6-dimethoxyphthalidyl) Anisole. XVIII.—A solution of 1.0 g. of 2,4-bis-(5,6-dimethoxyphthalidyl) phenol (XIII) was dissolved in 10% sodium hydroxide solution and shaken and warmed with 1.5 cc. of dimethyl sulfate. The solution remained clear because of the formation of the carboxyl group from the phthalide group by means of the alkali. Upon acidification, a precipitate formed which was filtered and washed with a 5% sodium hydroxide solution. The insoluble material was crystallized from alcohol and melted at 208–210°.

This product proved to be identical with the bis-dimethoxyphthalidyl compound obtained by the condensation of 2 moles of opianic acid and 1 mole of anisole.

2-Bromo-4,6-bis-(5,6-dimethoxyphthalidyl) Phenol. XVII.—A solution of 2.4 g. of 2,4-bis-(5,6-dimethoxyphthalidyl) phenol (XIII) was dissolved in 100 cc. of hot acetic acid, cooled somewhat and treated with 6 cc. of a molar solution of bromine in acetic acid. There thus precipitated 0.92 g. of the monobromo compound, which was purified by two crystallizations from acetic acid.

This substance was identical with that obtained by condensation of 2 moles of opianic acid with 1 mole of *o*-bromophenol.

4,6-bis-(4-bromo-5,6-dimethoxyphthalidyl)-2-methyl Phenol. XVI.—A mixture of 1.38 g. of 4,6-bis-(5,6-dimethoxy phthalidyl)-2-methyl phenol (XVI) in 50 cc. of acetic acid was refluxed for 2 hours with 7 cc. of a molar solution of bromine in acetic acid. On cooling, there deposited from the solution 0.11 g. of product, and from the filtrate, by evaporation and addition of alcohol, 0.26 g. more was obtained. This was diluted with 20 cc. of alcohol and filtered hot, and the insoluble residue crystallized from 250 cc. of alcohol. In this way 0.12 g. of pure material resulted, melting at 266–268°.

Since the *ortho* and *para* positions in the cresol nucleus were filled, it was assumed that this compound had the formula which has been assigned to it. In other words, the bromines in this case have entered the two opianic acid nuclei. In order to prove this point, 2 moles of bromo-opianic acid were condensed with *o*-cresol, by the general procedure mentioned above, and the same compound was obtained.

Benzyl-Benzic Acids

The method for the reduction of the substituted phthalides to the corresponding benzyl-benzoic acids was essentially the same as that used by Jacobson and Adams.^{1d,e,f}

A mixture of the phthalide (0.05 mole) and 10% sodium hydroxide solution (330 cc. of water and 60 cc. of 50% sodium hydroxide solution) was heated to boiling in a flask fitted with a reflux condenser and a mechanical stirrer. If the phthalide contained no phenolic hydroxyl or was insoluble in the sodium hydroxide solution, the mixture was refluxed until hydrolysis of the inner lactone took place and a clear solution resulted. Zinc dust (60–70 g.) was added to the solution in three or four portions at intervals of an hour. The first portions formed hard balls, but later portions formed a fine suspension of zinc, and the refluxing was continued for 10–20 hours. When the reaction was complete, the zinc was filtered off and the clear, colorless solution was slowly acidified with hydrochloric acid with efficient mechanical stirring. If a pure phthalide had been reduced a crystalline material separated, but it was often difficult to seed the crystallization, and even when seeded it frequently crystallized very slowly and a gum resulted. The gums were best separated with chloroform, the solutions dried and evaporated. The benzyl-benzoic acids from opianic acid were crystallized from toluene, while those from phthalaldehydic acid crystallized best from petroleum ether. The yields given in the table represent those of crystalline material.

During a study of the constitution of various phthalides it was hoped

that catalytic reduction could be employed for the replacement of the halogen in the phthalides by hydrogen. This replacement occurred but it was almost impossible to prevent the reduction from going further, with the formation of benzyl-benzoic acids and in some instances partial hydrogenation of the rings. Those reductions from which solid products were isolated are given below.

TABLE III
BENZYL-BENZOIC ACIDS (ALL WHITE)

7. $C_{17}H_{18}O_5$	Previously prepared by Jacobson with Adams			
8. $C_{16}H_{16}O_5$	74.35	5.92	74.68	5.87

Catalytic Reduction of 5,6-Dimethoxy-2-(4-hydroxy-3-bromophenyl) Phthalide.

XI.—A suspension of 2.89 g. of the phthalide in 100 cc. of 95% alcohol was reduced, using 0.1 g. of platinum-oxide catalyst³ and hydrogen under pressure. When the suspended phthalide was all in solution (3 hr., 45 min.), 3.6 molecular equivalents of hydrogen had been absorbed. The reduction was stopped, the catalyst filtered off and the alcohol removed by evaporation. Sodium carbonate dissolved nearly all of the gum, but a small amount (0.01 g.) remained insoluble. This melted at 156-180° and probably consisted mainly of 5,6-dimethoxy-2-(4-hydroxyphenyl) phthalide, but the small yield prevented further investigation. From the sodium carbonate-soluble gum, by crystallization from toluene, a small amount of material (less than 0.01 g.) melting at 171-172.5° was obtained, and this proved to be 5,6-dimethoxy-2-(4-hydroxybenzyl) benzoic acid. No other pure products were isolated.

Catalytic Reduction of 5,6-Dimethoxy-2-(2-hydroxy-3-methyl-5-bromophenyl) Phthalide.

XI.—A suspension of 6.8 g. of the phthalide, prepared as described by Jacobson and Adams,^{1d} in 200 cc. of alcohol was reduced catalytically, using 0.1 g. of catalyst. After 2 hours, the phthalide had all gone into solution, and 2.1 molecular

proportions of hydrogen had been absorbed. Evaporation of the solvent left a gum which partially crystallized. Crystallization from 50% acetic acid gave 3.07 g. of 5,6-dimethoxy-2-(2-hydroxy-3-methylbenzyl) benzoic acid (57%), which had previously been obtained by Jacobson and Adams¹⁴ using zinc and 10% sodium hydroxide as a reducing agent.

Catalytic Reduction of 5,6-Dimethoxy-2-(2-hydroxy-5-bromo-6-methylphenyl) Phthalide.—A suspension of 1.0 g. of the phthalide in 100 cc. of alcohol was reduced, using 0.1 g. of catalyst. The phthalide was all in solution at the end of 2 hours and the reduction was stopped. Evaporation of the alcohol and crystallization of the resulting gum from 10 cc. of toluene gave 0.17 g. (21%) of 5,6-dimethoxy-2-(2-hydroxy-6-methylbenzyl) benzoic acid (melting at 169–171°), which had previously been prepared by Jacobson and Adams.¹⁴

Catalytic Reduction of 2-(2-Methoxy-5-bromophenyl) Phthalide. XXIII.—A suspension of 4.0 g. of the pure phthalide in 100 cc. of alcohol was reduced, using 0.1 g. of catalyst. At the end of 1.75 hours, the material had all dissolved and 2.7 molecular proportions of hydrogen had been absorbed. Partial evaporation of the solvent and addition of water gave 1.4 g. (46%) of crystalline material, which was purified by recrystallization from petroleum ether (90–110°) and proved to be 2-(2-methoxybenzyl) benzoic acid. The pure material melted at 117–118° and was quickly soluble in 5% sodium carbonate solution.

Catalytic Reduction of 5,6-Dimethoxy-2-(2-hydroxy-4-methyl-5-bromophenyl) Phthalide and of 5,6-Dimethoxy-2-(2-hydroxyphenyl) Phthalide gave products from which no solid materials were isolated.

Summary

1. Opianic acid and *o*-phthalaldehydic acid condense with phenol and phenol derivatives to form substituted phthalides which may be converted to anthraquinone derivatives by reduction to substituted benzylbenzoic acids, ring closure and oxidation. This is an important method of synthesizing anthraquinone derivatives of definite structure, if the structure of the substituted phthalides is known with certainty. A study has, therefore, been made of the condensation of opianic acid and *o*-phthalaldehydic acid with phenol and phenol derivatives, and the structure of the resulting products has been demonstrated.

2. The condensation of opianic acid with phenol, anisole, *m*-cresol and *o*-cresol gives mixtures of *o*- and *p*-isomers and the isolation of a pure compound is difficult.

3. The use of bromine to block certain positions in the phenol or phenol derivative restricts or prevents the formation of isomers, and the resulting bromophthalides are also easier to crystallize. If a bromine atom was in the position *ortho* to the hydroxyl or methoxyl, the condensation was directed almost entirely to the *para* position in two cases studied (*o*-bromophenol and *o*-bromo-anisole). If a bromine atom was *para* to the hydroxyl or methoxyl, the condensation took place in the *ortho* position.

4. Attempts were made to remove the bromine from bromophthalides by catalytic reduction. The reductions, however, could not be stopped

at this stage, and as a result the corresponding benzyl-benzoic acids were the only compounds isolated and identified.

5. *o*-Phthalaldehydic acid was condensed with phenol, anisole and *p*-bromo-anisole to give the corresponding substituted phthalides.

6. In the condensation of opianic acid with phenol, anisole, *o*-cresol and *m*-cresol, by-products were formed. These were found to be derivatives of *bis*-phthalidyl phenol, formed by the condensation of two molecules of opianic acid with one of the phenol or phenol derivatives. By varying the conditions these could frequently be made the main product of reaction.

A STUDY OF THE SYSTEM: ACETANILIDE-PROPIONANILIDE

BY E. C. GILBERT AND LOYAL CLARKE

RECEIVED MAY 27, 1927

PUBLISHED SEPTEMBER 2, 1927

Incidental to a study of ketenes, Hurd¹ reports that fractional crystallization of mixtures of acetanilide and propionanilide yields a crystalline material melting sharply at 79.0–79.5°, but states that it is not a definite compound. The behavior would seem to indicate either that the material is a compound or a solid solution, and it was thought by the writers that a study of the freezing-point curves of mixtures of the two substances might furnish additional confirmation of his conclusions.

Experimental

Materials.—Propionanilide was prepared by refluxing redistilled aniline with propionic acid (Eastman Kodak Company). It was recrystallized from alcohol and carbon tetrachloride and melted at 105.0° (corr.).

The acetanilide (Merck) was recrystallized from alcohol, acetone and carbon tetrachloride and froze at 113.6° (corr.).

It was found early in the investigation that very small traces of water had a large effect on the freezing point, though not so much on the customary capillary tube melting point, so the materials were preserved at all times in a vacuum desiccator over sulfuric acid.

Manipulation.—Mixtures of approximately 10 g. each were made up by weight in a large stoppered test-tube, fused and then placed in a Dewar flask filled with hot water. A stirrer and an accurately calibrated thermometer were inserted and the temperature noted while the system cooled. The points at which the first solid phase separated out were obtained with ease and accuracy as there was always a small amount of supercooling, with the resultant rise of temperature. Where the per cent. of either component was large, the system was almost solid at the tem-

¹ Hurd, *THIS JOURNAL*, 45, 3095 (1923).

perature at which the second solid phase appeared and it was difficult to obtain equilibrium conditions and also contact of the mixture with the thermometer. Stirring, such as was permitted by the state of the mixture, aided. Without it the lower points of inflection on the curves fell many degrees too low. No difficulty was experienced with the middle range portions. All temperatures were corrected for emergent stem.

Results

The freezing points of various mixtures are given in Table I and the results are plotted graphically in Fig. 1.

Fig. 1.—Freezing-point composition curves for the system: acetanilide-propionanilide. ○ Freezing points of mixtures. ● Temp. of eutectic halting point.

Discussion

The completed freezing-point-composition curve of the system offers strong evidence of the formation of a compound of the two substances. The central portion is very flat, indicating that the compound is practically completely dissociated in the liquid state. In fact the temperatures along the middle branch of the curve are so close together that the maximum (if any) representing the exact freezing point of the compound cannot

TABLE I
FREEZING POINTS OF MIXTURES OF ACETANILIDE AND PROPIONANILIDE

Fig. 2.—Cooling curves. System: acetanilide-propionanilide. Mole % of propionanilide: I, 19.76; II, 42.76; III, 50.51; IV, 69.02. (Curve I made with air cooling.)

be determined accurately. These same temperatures $79.1-79.4^{\circ}$, however, coincide definitely with the melting point reported by Hurd,¹ $79.0-79.5^{\circ}$. From a consideration of the combustion analysis (and other data apparently not included in his article) Hurd concludes that the constant melting substance is a mixture or a solid solution, and the freezing point curve might almost be drawn on that basis, since the central portion is so flat. Consideration of the individual cooling curves (Fig. 2), however, each having two definite breaks, many times with supercooling in each, indicates clearly that in our work we are not dealing with a solid solution but with a compound which forms eutectic mixtures with the pure components. The lower break on each curve occurs within limits of the experimental technique, at the same temperature.

A study of the curves obtained by plotting "eutectic halting time" against composition leads to the conclusion, further, that the system forms no solid solutions, the solid phases consisting of the pure components and the compound.

Summary

1. The freezing-point curves of the system acetanilide-propionanilide have been determined.
2. The presence of a compound, almost completely dissociated in the liquid state, is indicated. The central portion of the curve is so flat that the composition of the compound cannot be determined with certainty.
3. The melting point of the compound is $79.2-79.4^{\circ}$.

HALOGENATED TERTIARY AMINES

By C. S. MARVEL, W. H. ZARTMAN AND O. D. BLUTHARDT

RECEIVED JUNE 6, 1927

PUBLISHED SEPTEMBER 2, 1927

A considerable number of halogenated amines are reported in the literature but as a general rule their properties have not been studied in detail. Gabriel¹ has prepared chloro-ethylamine and bromo-ethylamine and has shown that they undergo internal condensations very easily. Knorr² and his students have prepared a few derivatives of the type $XCH_2CH_2NR_2$ and $XCH_2CH_2CH_2NR_2$ and have studied their tendency toward ring formation. The first type forms six-membered piperazine rings and the second type forms eight-membered rings containing two nitrogen atoms. The delta halogenated butylamines have

¹ (a) Gabriel, *Ber.*, 21, 567, 574 (1888); (b) 22, 1140 (1889).

² (a) Knorr, *Ber.*, 37, 3511 (1904); (b) Knorr and Roth, *Ber.*, 39, 1424 (1906); (c) Hörlein and Kneisel, *Ber.*, 39, 1429 (1906).

been studied by several investigators³ who have found that they are easily converted to pyrrolidines.

More recently a patent⁴ describing some halogenated propyl- and butyl-diethylamines has appeared. Very little information is given concerning the properties of these compounds. They are said to react as normal alkyl halides in the alkylation of aceto-acetic ester.

From the properties previously recorded for this general class of compounds it was thought that they should be very interesting and useful reagents, if they could be obtained easily. Most of the previous investigators have not given complete directions and yields. Knorr and Roth^{5b} prepared 3-chloropropyl dimethylamine hydrochloride in yields of about 50% by heating 3-phenoxypropyl dimethylamine with concentrated hydrochloric acid in a sealed tube for several hours. We have found that by using hydrobromic acid to open similar ethers, the reactions can be carried out without the use of sealed tubes and yields of 80–88% of the hydrobromides of the bromo-alkylamines can be obtained. In this way 3-bromopropyl diethylamine and 4-bromobutyl diethylamine have been made readily available for use as reagents. The reactions used in the preparation of these two amines are as follows:

All of the reactions proceed smoothly to give good yields except in the case of the isolation of the free amine. There is considerable loss at this stage on account of the rapid formation of quaternary ammonium salt due to internal condensation.

The hydrobromide salts of the halogenated amines are very hygroscopic and very hard to purify. In the open air they take up water so rapidly that it seriously interferes with their purification and analysis. The crude salts can be used in absolute alcohol solution with two moles of sodium malonic ester to give typical malonic ester condensations. These reactions show that these compounds can be used as other alkyl halides in order to introduce the groups $-(\text{CH}_2)_3\text{N}(\text{C}_2\text{H}_5)_2$ and $-(\text{CH}_2)_4\text{N}(\text{C}_2\text{H}_5)_2$.

Experimental Part

3-Phenoxypropyl diethylamine.—To 73 g. of boiling diethylamine in a 500cc. flask fitted with a reflux condenser was added 100 g. of phenoxypropyl bromide over a period

³ (a) Gabriel, *Ber.*, 24, 3232 (1891). (b) Blank, *Ber.*, 25, 3044 (1892). (c) von Braun, *Ber.*, 39, 4121 (1906).

⁴ Eng. pat., 167,781; *Chem. Zentr.* (4), 1921, 1223.

of about thirty minutes. The reaction mixture was heated for about twelve hours when the reaction was complete and the contents of the flask appeared to be almost solid. The reaction mixture was extracted with 200 cc. of ether and the diethylamine hydrobromide was filtered and washed with about 100 cc. of ether. The ether extract and washings were combined and distilled. After the ether was removed, the phenoxypropyldiethylamine was distilled under reduced pressure. The yield was 80–123 g. (84–94% of the theoretical amount); b. p. 147–150° at 20 mm.; d_4^{20} , 0.9425; n_D^{20} , 1.4987. M_p , calcd., 64.39; observed, 64.43.

A small amount of the amine was dissolved in dry ether and converted to the hydrochloride by passing dry hydrogen chloride into the solution. The salt which separated melted at 98–102° with some decomposition.

Anal. (Volhard). Subs., 0.5071 g.: 19.93 cc. of 0.1034 *N* AgNO₃. Calcd. for C₁₁H₂₁ONCl: Cl, 14.56. Found: 14.41.

In a few runs of the amine another substance which was insoluble in ether and only slightly soluble in water was isolated. On recrystallization from hot water this product separated in long, white needles which melted at 77.5–79°. It seemed to be diphenoxypropyldiethylammonium bromide.

Anal. (Volhard). Subs. 0.7000 g.: 16.85 cc. of 0.0981 *N* AgNO₃. Calcd. for C₂₁H₂₅O₂NBr: Br, 18.95. Found: 18.89.

3-Bromopropyldiethylamine Hydrobromide.—A solution of 88 g. of phenoxypropyldiethylamine in 100 cc. of 40% hydrobromic acid was placed in a 500cc. flask, fitted by means of a ground glass connection to a 45cm. fractionating column which in turn was connected with a condenser set for distillation. The flask was placed in an oil-bath heated to 180–210°. Water, hydrobromic acid and phenol distilled from the reaction mixture. More hydrobromic acid was added from time to time until a total of 350–400 cc. was used. It was important to have an excess of hydrobromic acid present at all times as tarry products were formed when the reaction mixture was heated too long without the presence of hydrobromic acid solution. After about twelve to fifteen hours no more phenol came over in the distillate. The residue in the reaction flask was dissolved in about 100 cc. of water and most of the color removed by boiling with decolorizing carbon (Norit). The solution was then evaporated under reduced pressure until all of the water was removed. On standing the residue crystallized slowly. The color varied from gray to brown with different runs. The yield of crude product was about 88 g. (80% of the theoretical amount).

This product was very hygroscopic and attempts to recrystallize the material from solvents were not particularly successful on this account. It was found that dissolving the crude product in absolute butyl alcohol and precipitating with anhydrous ether gave colorless crystals. They were filtered out of contact with air and dried in a desiccator over phosphorus pentoxide and sulfuric acid. There was considerable loss in purification. This product melted at 91–94°.

Anal. (Parr bomb). Subs. 0.3155 g.: 22.88 cc. of 0.1010 *N* AgNO₃. Calcd. for C₇H₁₇NBr₂: Br, 58.18. Found: 57.29.

The low result for bromine was undoubtedly due to the presence of moisture. The range over which the product melted was also probably due to moisture taken up during handling of the product.

3-Bromopropyldiethylamine.—The crude hydrobromide was suspended in ether and this suspension was treated with a large excess of cold, concentrated sodium hydroxide solution. The ether solution was separated, dried over solid sodium hydroxide and the ether distilled under reduced pressure. The residue was distilled at 7 mm. and the fraction boiling at 60–64° was collected. The product came over clear but soon

became cloudy, due to formation of some of the quaternary ammonium compound produced by the reaction of one molecule of the bromo-amine with another. The physical properties and analysis were taken on samples freshly prepared and distilled; d_4^{25} , 1.1524; n_D^{25} , 1.4580. M_D , calcd., 46.40; observed, 45.81.

Anal. (Parr bomb). Subs. 0.8068 g.: 40.43 cc. of 0.1010 *N* AgNO₃. Calcd. for C₇H₁₈NBr: Br, 41.23. Found: 40.19.

On standing overnight the liquid amine changed to a solid quaternary ammonium salt, presumably the eight-membered ring analogous to that which Knorr and Roth^{5b} found to be formed from 3-chloropropyldimethylamine. The salt melted at 180–185° and the bromine could be titrated directly.

Anal. (Volhard). Subs. 0.4002 g.: 20.37 cc. of 0.1010 *N* AgNO₃. Calcd. for (C₇H₁₈NBr): Br, 41.23. Found: 41.12.

Diethyl 3-Diethylaminopropyl Malonate.—In a 1-liter round-bottomed flask connected to a good reflux condenser was placed 500 cc. of absolute ethyl alcohol which had been dried by refluxing with magnesium methyrate and distilling. Through the condenser 15 g. of sodium was added in small pieces as rapidly as possible. When the sodium had reacted, 120 g. of diethyl malonate was added and then a solution of 88 g. of crude bromopropyldiethylamine hydrobromide in 100 cc. of absolute alcohol. The mixture was refluxed for six to eight hours. Sodium bromide separated during this time. Most of the alcohol was distilled and the sodium bromide was dissolved in water. The ester layer was collected in ether and separated from the water layer. The amino ester was extracted from the ether with dilute hydrochloric acid solution, separated from the ether layer and then liberated with alkali. The amino ester was extracted with ether, the ether was distilled and then the residue was distilled under reduced pressure. The product boiled at 163–170° at 23 mm. The yield was 52 g. (62% of the theoretical amount); d_4^{25} , 0.9686; n_D^{25} , 1.4380. M_D , calcd., 74.28; observed, 73.98.

Anal. (Kjeldahl). Subs. 0.4212 g.: 18.08 cc. of 0.1745 *N* HCl. Calcd. for C₁₄H₂₇O₄N: N, 5.12. Found: 5.18.

4-Phenoxybutyldiethylamine.—In a 500cc. flask fitted with a reflux condenser was placed 85 g. of phenoxybutylamine and to it was added 56 g. of ethyl bromide and 21 g. of sodium hydroxide dissolved in 50 cc. of water. The reaction mixture was shaken for a short time. Considerable heat developed. The reaction mixture was allowed to stand for a day and then 56 g. of ethyl bromide and a solution of 25 g. of sodium hydroxide were added. The mixture was again allowed to stand for a day and finally refluxed for about a half hour to complete the reaction. Usually three layers appeared at this stage. The amine layer was on top, the aqueous solution was on the bottom and in between was an oily layer which was probably the quaternary ammonium salt. It was not purified. The amine layer was extracted with ether and the ether distilled. The residue was distilled under reduced pressure and the product boiling at 152–158° at 21 mm. was collected. The yield was 83–91 g. (73–80% of the theoretical amount). Occasionally the yields were higher or lower depending on the amount of quaternary ammonium salt formed; d_4^{25} , 0.9424; n_D^{25} , 1.4975. M_D , calcd., 69.01; observed, 68.51.

4-Bromobutyldiethylamine Hydrobromide.—This product was prepared by the same method used for the corresponding propyl compound. From 100 g. of phenoxybutyldiethylamine and 350 cc. of 40% hydrobromic acid, there was obtained 103–115 g. (79–88% of the theoretical amount) of crude bromobutyldiethylamine hydrobromide. This product was also very hygroscopic and consequently very hard to purify. After crystallizing from anhydrous butyl alcohol and anhydrous ether, crystals which melted at 62–68° were obtained. These were dried in a desiccator over phosphorus pentoxide and sulfuric acid.

Anal. (Parr bomb). Subs. 0.5864 g.: 39.74 cc. of 0.1010 *N* AgNO₃. Calcd. for C₆H₁₁NBr: Br, 55.36. Found: 54.75.

4-Bromobutyldiethylamine.—The free bromo-amine was isolated as described for the propyl compound. It boiled at 68–70° at 6 mm.; d_4^{25} , 1.0187; n_D^{25} , 1.4415. *M_D*, calcd., 52.38; observed, 53.92.

Anal. (Parr bomb). Subs. 0.3197: 15.43 cc. of 0.1010 *N* AgNO₃. Calcd. for C₆H₁₃NBr: Br, 38.46. Found: 38.49.

This amine gradually became opaque and after about twelve hours crystals of the quaternary ammonium compound, which was presumably diethyl pyrrolidinium bromide, began to separate. This product melted at 170–175°.

Anal. (Volhard). Subs. 0.2958 g.: 14.07 cc. of 0.1010 *N* AgNO₃. Calcd. for C₆H₁₃NBr: Br, 38.46. Found: 38.43.

Diethyl 4-Diethylaminobutyl Malonate.—This ester was prepared by the same method used for the corresponding propyl derivative. From 16 g. of sodium, 600 cc. of absolute alcohol, 128 g. of diethyl malonate and 100 g. of crude bromobutyldiethylamine hydrobromide, there was obtained 23 g. (23% of the theoretical amount) of the amino malonic ester, which boiled at 170–175° at 24 mm.; d_4^{25} , 0.9621; n_D^{25} , 1.4468. *M_D*, calcd., 78.90; observed, 80.46.

Anal. (Kjeldahl). Subs., 0.4047 g.: 17.93 cc. of 0.1745 *N* HCl. Calcd. for C₁₆H₂₇O₄N: N, 4.88. Found: 4.90.

Summary

3-Bromopropyldiethylamine and 4-bromobutyldiethylamine have been prepared by general reactions and some of their properties and reactions have been studied.

ALKYL-NITROGUANIDINES

BY TENNEY L. DAVIS AND STEWART B. LUCE

RECEIVED JUNE 11, 1927

PUBLISHED SEPTEMBER 2, 1927

Nitroguanidine in aqueous solution at 60–70° appears to dearrange in the expected manner¹ to produce, on the one hand, ammonia and nitrocyanamide and, on the other, nitro-amide and cyanamide. If the solution is digested with ammonia, the ammonia inhibits the first of the above-mentioned dearrangements and combines with the cyanamide produced by the second to form guanidine, while the nitro-amide which is liberated at the same time decomposes to produce nitrous oxide, which escapes from the solution. By working with ammonium carbonate, guanidine carbonate is obtained in a yield amounting to 90% of the theoretical, and the by-products are a small amount of melamine from the polymerization of cyanamide, and a smaller amount of urea, from the cyanic acid which results apparently from the loss of nitrous oxide from nitrocyanamide. With aniline a small amount of phenylguanidine is produced, but

¹ Davis and Abrams, *Proc. Am. Acad. Arts Sci.*, 61, 437 (1926).

the principal product is phenylurea. With an aliphatic amine, such as methylamine, a small amount of the alkylguanidine is probably formed, a considerable amount of the alkylurea is produced but the principal product is the alkylnitroguanidine, evidently formed by the combination of the amine with the nitrocyanamide from the rearrangement.

Methyl-, ethyl-, *n*-butyl- and benzylnitroguanidine have been prepared previously and described elsewhere.¹ In the present paper we wish to report a number of other alkylnitroguanidines, and include, for completeness and for comparison, a description of those which have been previously reported. The transformations of these substances are being studied in this Laboratory.

In this work, α -nitroguanidine² was used, for it had been found earlier that both forms of nitroguanidine yield the same methylnitroguanidine. Slightly more than one molecular proportion of nitroguanidine was added to a 10% aqueous solution of the primary amine, and the mixture was heated in the water-bath at 60–70° for 30 or 40 minutes or until almost all of the nitroguanidine had disappeared. Ammonia came off abundantly. The solution was chilled and filtered, and the filtrate was evaporated to dryness in a current of air at laboratory temperature. The combined residues were extracted with dry alcohol at 70° and yielded an insoluble portion which consisted of unchanged nitroguanidine generally associated with considerable amounts of guanidine carbonate, and a solution from which the pure alkylnitroguanidine was obtained by recrystallization, in yields varying from 30 to 50% of the theoretical.

Dimethylamine is the only secondary amine with which we have succeeded in carrying out the reaction. It required more vigorous treatment than the primary amines, a 20% aqueous solution needing about 2 hours' digestion at 70–80° to cause the nitroguanidine to go into solution.

TABLE I

¹ Davis, Ashdown and Couch, *THIS JOURNAL*, 47, 1063 (1925).

The alkylnitroguanidines are colorless, crystalline solids, moderately soluble in alcohol, insoluble or slightly soluble in cold water, more soluble in hot, and insoluble or slightly soluble in ether. Benzylnitroguanidine is the least soluble, requiring about 1050 parts of cold water and about 200 parts of boiling water for solution, and is sparingly soluble even in hot alcohol. It chars with concd. sulfuric acid. The others dissolve readily in concd. sulfuric acid, give a blue color with a solution of diphenylamine in that substance, and give up their nitro group nitrogen quantitatively in the nitrometer. They decompose slowly when boiled in aqueous solution.

THE CATALYTIC REDUCTION OF *D*-GLUCONIC ACID TO *D*-GLUCOSE

BY J. W. E. GLATTFELD AND EDNA H. SHAVER¹

RECEIVED JUNE 18, 1927

PUBLISHED SEPTEMBER 2, 1927

The work reported below is an outgrowth of the efforts that are being made in this Laboratory to prepare and study the C₄-saccharinic acids.² This preparation work has now progressed to such an extent that the possibility of extending it to the C₆-saccharinic acids is being considered. This extension would involve as one step the reduction of the C₄-acids to the corresponding aldehydes. The realization of the extension depends, in large measure, on the possibility of discovering a practical procedure for this reduction. Of possible reduction methods the catalytic hydrogenation of the acids in the presence of oxides of platinum seemed to hold promise and the work reported below was done to test it. In order to conserve material, the easily obtained *D*-gluconic acid was used instead of the C₄-saccharinic acids for this preliminary study.

W. E. Cake³ has recently stated that glucose in neutral solution is not reduced by hydrogen in the presence of platinum black. It occurred to us, therefore, that if the reduction of the aldonic acids could be effected by hydrogen in the presence of platinum oxides in neutral or slightly acid solution (that is, with no added acid or very little), the yield of aldoses

¹ The dissertation of which this paper is a condensation was presented by Edna H. Shaver in partial fulfilment of the requirements for the degree of Doctor of Philosophy, in the University of Chicago. Some of the material reported in this paper was presented at the meeting of the Midwest Sections of the American Chemical Society in Chicago, May 27-28, 1927.

might be very good because of the fact that the aldoses might not be reduced under these conditions to alcohols.

It was found to be possible to reduce *d*-gluconic acid to *d*-glucose in 14–28% yield (measured as osazone) by this method. A few experiments were tried with mannonic acid and with galactonic acid. With mannonic acid under what seemed to be the same conditions that had proved favorable for the reduction of gluconic acid to glucose, a yield of only 0–2% of mannose (as osazone) was obtained. Galactonic acid in water solution was reduced to dulcitol in 30–45% yield. The conclusion is therefore reached that different aldonic acids require different experimental conditions for successful reduction to the aldoses and, therefore, that the method may prove to be of some value in individual cases with the C₄-saccharinic acids.

Experimental Part

Materials and Apparatus.—The calcium gluconate used as starting material was made by the oxidation of glucose by means of bromine. The purified product showed only a trace of bromide ion, and did not reduce Fehling's solution; analysis for calcium showed it to be practically pure (calcd. for C₁₂H₂₂O₁₄Ca: Ca, 9.31. Found: 9.28, 9.23). The catalyst was prepared by the method of Vorhees and Adams⁴ except that about 0.2 g. of ferrous sulfate per 3 g. of platinum⁵ was added with the sodium nitrate to the chloroplatinic acid solution. The hydrogen used came from a commercial tank of the gas; it was used without purification. The hydrogenating apparatus was that described by Skita⁶ and modified by Vorhees and Adams.⁴

The Procedure.—The sample of calcium gluconate (6.2 g., Col. 2 of table below) was dissolved in about 10 parts of water and such an amount of a sulfuric acid solution (sp. gr. 1.525), (Col. 3) added as to leave the solution finally in the desired condition of acidity with respect to sulfuric acid (Col. 4). The filtrate from the calcium sulfate was concentrated on the water-bath, made up to volume (25 cc.) and the specific rotation determined (Col. 5). The solution was transferred to the reaction bottle, 1 g. of catalyst added and the hydrogenation started. The air was not removed from the reaction bottle before admission of hydrogen.⁷ The bottle was shaken vigorously by a mechanical device for three hours; then another 1g. portion of catalyst was added and the shaking continued for two hours when another 1g. portion of catalyst was introduced and the hydrogenation continued for another two-hour period. The pressure in the reaction bottle slowly dropped during the seven-hour period from 17 pounds to 10. The reaction mixture was then filtered, the volume of the filtrate measured and the specific rotation determined (Col. 6).

Glucosazone.—The reduced reaction solution (from 6.2 g. of calcium gluconate) was made neutral to litmus with sodium hydroxide, and 6 cc. of phenylhydrazine and 4 cc. of glacial acetic acid were added. The customary procedure for osazone formation yielded 4.2 g. of air-dry crystals which were treated with 50 cc. of water. The mixture was heated to boiling and subjected to filtration while hot. The filtrate deposited crystals (Col. 7)

⁴ Vorhees with Adams, *THIS JOURNAL*, **44**, 1402 (1922).

⁵ Carothers and Adams, *ibid.*, **45**, 1071 (1923).

⁶ Skita, *Ber.*, **45**, 3594 (1912).

⁷ Because of the small volume of air in the bottle this seemed a safe procedure in this case; if a large reaction vessel is used the air should be removed before admission of hydrogen because of the possibility of explosion.

which were shown to be the phenylhydrazide of gluconic acid. The material insoluble in the 50 cc. of hot water (Col. 8) was shown to be glucosazone. It was twice recrystallized from 30% alcohol and then melted at 207°, as did also a mixture of this compound with known glucosazone. This fact, together with the analysis of samples (calcd. for $C_{12}H_{22}O_4N_4$: H, 6.19; C, 60.29. Found: 6.19, 6.15, 60.19, 60.23) should be conclusive evidence of the identity of the compound.

This procedure was carried out many times. The table below summarizes the data from six experiments which are fairly representative of the results obtained.

TABLE I
REDUCTION OF *d*-GLUCONIC ACID UNDER 10-17 POUNDS' PRESSURE

Expt. No.	Calcium gluconate, g.	H ₂ SO ₄ , cc. (sp. gr. 1.825)	Theoretical H ₂ SO ₄ if all calcium pptd.	Sp. rot. before reduction	Sp. rot. after reduction	Gluconic phenylhydrazide, g.	Glucosazone, g.	Yield of hydrazide, %	Yield of osazone, %
1	6.2	1.5	0	+12.8	+23.5	2.0	2.1	24.3	20.3
2	6.2	1.5	0	+12.8	+23.5	2.4	2.1	29.1	20.3
3	6.2	1.5	0	+12.8	...	2.5	2.9	30.3	28.1
4	6.2	1.4	Incomplete precipitation	+12.8	+23.8	2.6	2.6	31.5	25.1
5	6.2	1.3	Incomplete precipitation	...	+22.5	2.6	2.6	31.5	25.1
6	6.2	2.0	0.4	3.2	1.5	38.8	14.5

Glucose Oxime.—The gluconic acid obtained from 6.2 g. of calcium gluconate by the addition of the theoretical amount of sulfuric acid was hydrogenated as described above. The filtrate from the catalyst was neutralized with sodium hydroxide and yielded with hydroxylamine 0.15 g. of crystals, m. p. 137°; the melting point of a mixture with known glucose oxime was also 137°.

Isolation and Identification of Glucose

For the isolation of glucose, the filtrate from the catalyst was heated at 100° for half an hour with excess calcium carbonate. The filtrate from the carbonate was concentrated under reduced pressure to a sirup which was repeatedly extracted with boiling absolute alcohol. The alcoholic solution was concentrated under reduced pressure to a sirup, the sirup dissolved in water, the solution again treated with calcium carbonate and the procedure just outlined carried out once more. The alcoholic solution this time was treated with a small amount of ether and allowed to stand for several days with occasional addition of small amounts of ether until such addition caused no further cloudiness. Warty aggregates of crystals appeared on the sides of the test-tubes. The crystals from a large number of such experiments were combined and studied.

Melting Point.—Repeated solution of the crude crystals (m. p. 140°) in absolute alcohol and precipitation with ether yielded crystals which melted at 146°; this melting point could not be raised. A mixture of the purified crystals with anhydrous glucose (m. p. 146°) also melted at 146°.

Rotation.—Four-tenths of a gram of crystals of m. p. 146° in 10 cc. of water solution gave α in a 1-dcm. tube, 20 minutes after solution,

+2.45°; 2 hours after solution, +2.14; 24 hours after solution, +2.08 with no further change in rotation. The corresponding specific rotations are +61.2, +53.5, +52.0. (The equilibrium specific rotation of glucose is +52.6.)

Titration.—Four cc. of the solution used for rotation was made up to 50 cc.; 14.8 cc. of this solution was required for the complete precipitation of the copper in 10 cc. of Fehling's solution of such strength that 10 cc. was equivalent to 0.047 g. of glucose; purity of sample, 99.2%.

Anal. Samples of m. p. 146° were analyzed after repeated purifications by means of solution in absolute alcohol and precipitation with ether. Calcd. for $C_6H_{12}O_6$: H, 6.72; C, 39.97. Found: 6.30, 6.21, 6.18, 6.24, 38.78, 38.87, 38.64, 39.10.

The combustion data were very puzzling in the light of the very good agreement of all other data with those for pure *d*-glucose. The conclusion was finally reached that the impurity present must be an inorganic compound which clung tenaciously to the glucose crystals through all purifications. A sample of 0.4459 g. (m. p. 146°) was ignited, therefore, and found to leave a glassy residue of 0.0100 g. If the impurity were absolutely free from carbon, this small amount of residue might adequately account for the low results of combustion.

Glucosazone from Crystalline Product.—In view of the unsatisfactory combustion results, a characteristic glucose derivative from the crystalline product of the hydrogenation was prepared. From 0.34 g. of crude crystals (m. p. 140°), there was obtained 0.29 g. of crude osazone which, after one recrystallization from 30% alcohol, melted at 207°. This melting point was not lowered by addition of crystals of known glucosazone of m. p. 207°. Furthermore, the analysis of this product gave figures that indicated it to be glucosazone (calcd. for $C_{12}H_{17}O_4N_4$: H, 6.19; C, 60.29. Found: 6.51, 6.34, 60.42, 60.40.).

Summary

The results of a study of the catalytic reduction of *d*-gluconic acid to *d*-glucose in water solution under 10–17 pounds' pressure and in the presence of a platinum oxide catalyst are reported. From the reaction mixture, there was isolated (a) glucosazone in 14–28% yield, (b) glucose oxime and (c) crystalline *d*-glucose.

**THE C₄-SACCHARINIC ACIDS. IV. THE PREPARATION OF THE
 TWO *dl*-1,2-DIHYDROXYBUTYRIC ACIDS**

By J. W. E. GLATTFELD AND SYBIL WOODRUFF¹

RECEIVED JUNE 18, 1927

PUBLISHED SEPTEMBER 2, 1927

As has been stated in previous papers, the preparation of the C₄-saccharinic acids has been undertaken in order to supply data on these acids that may be of value to workers in the sugar field. Our main object, however, has been to supply these data as a preliminary to a study of the mechanism of saccharinic acid formation from the tetroses and other simple sugars, which study it is hoped to make in this Laboratory when the necessary information as to the properties of the theoretically possible products of such action has been obtained.

The work reported in this paper is a continuation of previously reported work. Of the eleven theoretically possible C₄-saccharinic acids (the dihydroxybutyric and -isobutyric acids), the two active 2,3-dihydroxybutyric acids,² the two active 1,3-dihydroxybutyric acids³ and *dl*-1,2-dihydroxyisobutyric acid,⁴ have already been prepared and studied to some extent. This paper reports the preparation of the two *dl*-1,2-dihydroxybutyric acids which have the following formulas:

Discussion of the Literature

None of the work recorded in the literature had as its direct object the study of the acids themselves; their preparation was incidental to other work. Consequently, no thorough comparative study of the acids has been made and the literature leaves the properties and even the separate identities of the two true *dl*-1,2-dihydroxybutyric acids in doubt.

If we pass over the first three papers in the field,⁵ as well as a paper by Faber and Tollens,⁶ we come to two papers by Melikoff⁷ in which reports

¹ The dissertation of which this paper is a condensation was presented by Sybil Woodruff in partial fulfillment of the requirements for the degree of Doctor of Philosophy, in the University of Chicago.

are made of studies of the chlorohydroxybutyric acids formed by the addition of hypochlorous acid to crotonic and *isocrotonic* acids and of the glycidic (oxygen-ring) and methylglycerinic acids which are derived therefrom. With crotonic acid as starting material, Melikoff isolated crystalline α -chloro- β -hydroxybutyric acid (m. p. 62–63°), crystalline β -methylglycidic acid (m. p. 84°) and crystalline β -methylglycerinic acid (m. p. 80°). *Isocrotonic* acid under similar treatment gave three chlorohydroxybutyric acids of which the one of m. p. 80.5° gave a liquid β -methylisoglycidic acid which, in turn, gave a β -methylisoglycerinic acid of m. p. 45°. Aside from an account of the preparation of the ethyl ester of β -methylglycerinic acid⁸ and an abstract of a paper in the Russian Journal,⁹ no other references could be found to the dihydroxybutyric acids made by the hypochlorous acid method.

One other important method of preparation has been used by two groups of workers. This involves the direct oxidation of salts of the crotonic acids by means of permanganate. Fittig and Kochs¹⁰ obtained by this process an anhydrous dihydroxybutyric acid of m. p. 74–75° and from *isocrotonic* acid a liquid dihydroxybutyric acid. In 1904, Morrell and Hanson¹¹ resolved the β -methylglycerinic acid of Fittig and Kochs, and found the *l*-form to melt at 74–75° and to have a specific rotation in aqueous solution of -13.51° .

It may be said, then, that four presumably different 1,2-dihydroxybutyric acids have been reported in the literature. It is felt that the experimental work reported below definitely establishes the fact that the two *dl*-1,2-dihydroxybutyric acids are those of melting points 81.5 and 74.5°.

Experimental Part

As neither Melikoff nor Kochs records the yields obtained and as Melikoff did not even give quantities of materials used, the details of the published methods had to be worked out and the procedures found by us to give the best results are recorded below. A third method of oxidation—one which yielded the same acid as the permanganate method—was also developed. Finally, a thorough comparative study of the two acids and of some of their derivatives was made in order to establish beyond reasonable doubt the fact that the acids obtained are really different and are the two *dl*-1,2-dihydroxybutyric acids sought.

Preparation of the Acids

I. The Hypochlorous Acid Method of Preparation.—The essential steps in this method of preparation are indicated below.

⁸ Melikoff and Zelinsky, *Ber.*, 21, 2052 (1888).

⁹ Melikoff, *J. Russ. Phys. Chem. Soc.*, 1884 (I), 517–544 (*Ber.*, 17 (R), 420 (1884)).

¹⁰ Fittig and Kochs, *Ann.*, 268, 1 (1892).

¹¹ Morrell and Hanson, *J. Chem. Soc.*, 85, 197 (1904).

Into a solution of 400 g. of crotonic acid (m. p. 71–72°) in 8 liters of water, mechanically stirred and kept at a temperature of 5–9°, was passed a slow stream of a mixture of chlorine and air (1 to 1) until the reaction mixture no longer decolorized permanganate solution and barely colored a dilute starch-iodide solution (7 to 14 hours; our experiments indicate the longer time is preferable). The solution was concentrated at 25 mm. to 2 liters and divided into 2 equal parts; the history of only one of these is important for this report. This 1 liter of reaction solution was extracted twice with 750 cc. of ether, the ether removed at atmospheric pressure and the residue (368 g. of crude chlorohydroxybutyric acid) in 500 cc. of water treated in the cold with small portions of barium carbonate until effervescence ceased (231 g. of carbonate). The mixture was heated almost to boiling and filtered; the filtrate deposited, in several crops, a total of 375 g. of crude salt (78% of theoretical calculated from crotonic acid). Thirty g. of the barium salt (after one recrystallization) was dissolved in 240 cc. of water and the solution maintained at 70–80° while a water suspension of the silver oxide from 26 g. of silver nitrate was added in very small portions followed by shaking after each addition (two hours for addition). (Great care is necessary during this stage. When most of the silver oxide has been added the silver chloride should be removed, the further addition of oxide made very carefully and the addition stopped when the first appearance of suspended free silver, which gives a pink tinge of translucency to the solution, is noted.) The barium was quantitatively removed from the filtered solution with 8 *N* sulfuric acid and the filtrate from the barium sulfate subjected to distillation to dryness at 25 mm. from a water-bath at 45°. The almost colorless sirup weighed 14.6 g. (84% calcd. from barium salt) and crystallized spontaneously after 24 hours in a desiccator.

The semi-solid mass was transferred to a suction filter and as much liquid as possible removed. A total of 87.0 g. of crude acid thus gave 43.9 g. of fairly dry crystals; m. p., 71–80°. Fourteen g. of these crystals in 5 cc. of water gave, in two crops, 7.3 g. of acid of m. p. 81.5° (the melting point of the acid was very sharp but, because of the very great difficulty in recrystallization, it is possible that the true melting point of the acid may be a little higher). The acid was not hygroscopic, was soluble in alcohol, glacial acetic acid and hot ethyl acetate; insoluble in cold ethyl acetate and ether. The air-dry crystals lost only 0.16% in weight when dried to constant weight over phosphorus pentoxide.

Titration. Subs., 0.2267, 0.4800; 18.94, 39.73 cc. of 0.1 *N* alkali (phenolphthalein). Calcd. for C₄H₅O₄: 18.88, 39.98 cc.

Anal. Subs., 0.1537, 0.1490: H₂O, 0.0918, 0.0898; CO₂, 0.2250, 0.2178. Calcd. for C₄H₅O₄: H, 6.71, C, 39.99. Found: 6.68, 6.74, 39.93, 39.87.

II. The Permanganate Method of Preparation.—To a solution of 20 g. of crotonic acid (m. p. 71–72°) and 22.8 g. of barium carbonate in 200 cc. of water, was added 400 cc. of a saturated solution of barium hydroxide and then 1 liter of water. The milky solution, chilled in ice water, was treated drop by drop with 2 liters of an ice-cold solution of barium permanganate which contained 43.6 g. of the salt; time of addition,

are made of studies of the chlorohydroxybutyric acids formed by the addition of hypochlorous acid to crotonic and *isocrotonic* acids and of the glycidic (oxygen-ring) and methylglycerinic acids which are derived therefrom. The air-dry crystals lost only 0.16% in weight when dried to constant weight over phosphorus pentoxide.

Titration. Subs., 0.2267, 0.4800; 18.94, 39.73 cc. of 0.1 N alkali (phenolphthalein). Calcd. for C₄H₅O₄: 18.88, 39.98 cc.

Anal. Subs., 0.1537, 0.1490: H₂O, 0.0918, 0.0898; CO₂, 0.2250, 0.2178. Calcd. for C₄H₅O₄: H, 6.71, C, 39.99. Found: 6.68, 6.74, 39.93, 39.87.

II. The Permanganate Method of Preparation.—To a solution of 20 g. of crotonic acid (m. p. 71–72°) and 22.8 g. of barium carbonate in 200 cc. of water, was added 400 cc. of a saturated solution of barium hydroxide and then 1 liter of water. The milky solution, chilled in ice water, was treated drop by drop with 2 liters of an ice-cold solution of barium permanganate which contained 43.6 g. of the salt; time of addition,

three hours. The filtered reaction mixture was then concentrated to 800 cc. at reduced pressure from a water-bath at 50–55°, filtered and treated with enough 8 *N* sulfuric acid exactly to precipitate the barium. The filtrate from the barium sulfate was concentrated as above to 200 cc., twice extracted with 150cc. portions of ether, subjected to steam distillation until the distillate became neutral to litmus and subjected to distillation at 15–20 mm. (water-bath at 50–55°) as long as moisture distilled. The sirup thus obtained weighed 7 g. (25% yield) and crystallized within an hour when "seeded" with a crystal of acid made by the osmium tetroxide method (see below).

The 7 g. of acid was recrystallized from 4 cc. of water (solution chilled in ice-salt mixture) and yielded as the first crop 2.3 g. of crystals (m. p., after drying over phosphorus pentoxide, 73.5–74.5°). The air-dry acid was shown to contain 1 molecule of water of crystallization which it lost in a desiccator over phosphorus pentoxide (loss 12.67%). The acid was soluble in alcohol and hot ethyl acetate but insoluble in ether and cold ethyl acetate. The acid, dried over phosphorus pentoxide, was used in the analytical work.

Titration. Subs., 0.2873, 0.3272: 23.92, 27.25 cc. of 0.1 *N* alkali (phenolphthalein). Calcd. for $C_4H_5O_4$: 23.95, 27.27 cc.

Anal. Subs., 0.2901: H_2O , 0.1735; CO_2 , 0.4241. Calcd. for $C_4H_5O_4$: H, 6.71; C, 39.99. Found: 6.65, 39.88.

III. The Osmium Tetroxide Method of Preparation

A solution of 100 g. of crotonic acid (m. p. 71–72°) and 189.2 g. of potassium chlorate in 1500 cc. of water, to which had been added 150 cc. of a water solution of osmium tetroxide which contained about 0.15 g. of the tetroxide, was kept in a water-bath at 50° for eight hours, when a test for completion of reaction was positive. For details of this test, as well as for a complete discussion of this method of oxidation as applied to fumaric and maleic acids, including caution as to the use of osmium tetroxide, the reader is referred to a paper by Milas and Terry.¹² The cooled solution was twice extracted with 500 cc. of benzene in order to remove the catalyst and concentrated at reduced pressure (15–20 mm.) to dryness. The residue was treated with 450 cc. of absolute alcohol, the solution filtered and again concentrated to dryness at reduced pressure. The residue was dissolved in 300 cc. of water and barium carbonate added in slight excess, the mixture heated to boiling, insoluble matter removed and the solution allowed to cool. A total of 156 g. of crude barium salt was thus obtained. Six recrystallizations of this crude salt from water were necessary to remove chloride completely; 76.2 g. of pure salt was obtained which gave, after the removal of barium in the usual way, 24 g. of sirup which crystallized completely when "seeded" (17% yield calcd. from crotonic acid).

The 24 g. of crude crystalline product was recrystallized from 10 cc. of water and yielded 13 g. of acid as a first crop. This acid contained 1 molecule of water of crystallization which it lost to the air in six days (loss 12.82%). The acid, after drying to constant weight in a desiccator over phosphorus pentoxide, melted at 73.5–74.5°. Titration and analysis for carbon and hydrogen gave, in duplicate, results almost identical with those for the acid obtained by the permanganate method.

Derivatives of the Acids

In order to save space the dihydroxybutyric acids prepared by the three different procedures outlined above will be referred to henceforth in this paper as Acid-HOCl, Acid-MnO₄ and Acid-OsO₄, respectively.

¹² Milas and Terry, *This Journal*, **47**, 1412 (1925).

DERIVATIVES OF ACID-HOCl. **Phenylhydrazide**,¹³ C₁₀H₁₄O₃N₂·H₂O.—A mixture of 2 g. of acid (m. p. 81.5°) and 3 g. of phenylhydrazine in 2 cc. of absolute alcohol, warmed for half an hour at 75°, yielded 3.4 g. of crude crystals; twice recrystallized from absolute alcohol these yielded 2 g. of vacuum-dry substance of m. p. 103°. This compound was an ivory-white, granular powder even when it separated slowly from alcohol. Calcd. for C₁₀H₁₄O₃N₂·H₂O: N, 12.28; H, 7.07; C, 52.61. Found: 12.47, 12.25, 7.27, 51.98.

***o*-Tolylhydrazide**, C₁₁H₁₆O₃N₂·H₂O.—This compound was made in the same way as the phenylhydrazide: 2 g. of acid and 3.4 g. of *o*-tolylhydrazine (m. p. 59°) in 4 cc. of absolute alcohol gave 2.9 g. of product; twice recrystallized from 15 cc. of absolute alcohol, this crude product yielded 0.5 g. of substance, m. p. 103°. The compound separated in recrystallizations as a powder. Calcd. for C₁₁H₁₆O₃N₂·H₂O: N, 11.57. Found: 11.52, 11.57.

Barium Salt (C₄H₇O₄)₂Ba.—Three g. of recrystallized acid (m. p. 81.5°) in 7 cc. of water was treated in the cold with 2.4 g. of barium carbonate; the filtered solution was concentrated at reduced pressure to 3 cc. and poured into 25 cc. of absolute alcohol. The precipitated salt was rendered crystalline by trituration in absolute alcohol; 3.5 g. of powdery salt (desiccator-dry) was thus obtained. It could not be recrystallized from water. The salt was dried at 110°. Calcd. for (C₄H₇O₄)₂Ba: Ba, 36.58. Found: 36.16, 36.11.

Silver Salt, C₄H₇O₄Ag.—Three g. of acid (m. p. 81.5°) in 25 cc. of hot water was treated with 3.3 g. of silver carbonate. As the hot filtrate cooled, it deposited 2 g. of white powder. The salt decomposes somewhat if its aqueous solution is heated. Calcd. for C₄H₇O₄Ag: Ag, 47.53. Found: 47.44, 47.42.

DERIVATIVES OF ACID-MnO₄. **Phenylhydrazide**, C₁₀H₁₄O₃N₂·H₂O.—From 2 g. of acid (m. p. 73.4–74.5°) 3.7 g. of white, fluffy, fine needles was obtained; m. p. of purified product, 129.5°. This compound could be recrystallized from 5 parts of absolute alcohol, whereas only 1 part of absolute alcohol could be used with the phenylhydrazide of Acid-HOCl. Calcd. for C₁₀H₁₄O₃N₂·H₂O: N, 12.28; H, 7.07; C, 52.61. Found: 12.31, 12.64; 7.27; 51.53.

***o*-Tolylhydrazide**, C₁₁H₁₆O₃N₂·H₂O.—One and five-tenths g. of acid (m. p. 73.5–74.5°) gave 3.0 g. of product as ivory-white, glistening leaflets. Two recrystallizations from 15 cc. of absolute alcohol gave 1.3 g. of product; m. p., 111.5°. Calcd. for C₁₁H₁₆O₃N₂·H₂O: N, 11.57; H, 7.49; C, 54.52. Found: 11.57, 7.63, 53.69.

DERIVATIVES OF ACID-OSO₄. **Phenylhydrazide**, C₁₀H₁₄O₃N₂·H₂O.—The results of this preparation were identical with those of the preparation of the phenylhydrazide of the Acid-MnO₄ as regards properties of product, behavior and yield. The purified phenylhydrazide melted at 129.5°. Calcd. for C₁₀H₁₄O₃N₂·H₂O: N, 12.28. Found: 12.86, 12.57.

***o*-Tolylhydrazide**, C₁₁H₁₆O₃N₂·H₂O.—This derivative was also similar in method of preparation, yield and properties to that made from the Acid-MnO₄. It melted at 111.5°. Calcd. for C₁₁H₁₆O₃N₂·H₂O: N, 11.57; H, 7.49; C, 54.52. Found: 11.42, 11.39, 7.59, 53.80.

Barium Salt, (C₄H₇O₄)₂Ba.—Five g. of acid (m. p. 74.5°) in 15 cc. of cold water was treated with 4 g. of barium carbonate in portions. The thick paste was heated; the hot filtrate deposited 5 g. of white, needle-like crystals. These were dried at 110°. Calcd. for (C₄H₇O₄)₂Ba: Ba, 36.58. Found: 36.51, 36.62.

¹³ The "phenylhydrazide" obtained here, and likewise from the acids made by the other two procedures, may have been the phenylhydrazine salt of the acid and not the true phenylhydrazide with one molecule of water of crystallization. Because of the stability and general properties of the product, we are inclined to think it was the true phenylhydrazide.

Silver Salt, $C_6H_7O_4Ag$.—A hot solution of 4 g. of acid (m. p. 74.5°) in 50 cc. of water was treated with 4.5 g. of silver carbonate in small portions. The hot filtrate deposited 2 g. of large, glistening, silver-white leaflets. Calcd. for $C_6H_7O_4Ag$: Ag, 47.53. Found: 47.53, 47.64.

Comparison of the Properties of the Acids Made by the Three Different Methods and of their Derivatives

So far as the properties of the Acid- MnO_4 and the Acid- OsO_4 and their derivatives were studied, there is every indication that these acids are identical.

COMPARISON OF MELTING POINTS

Compound	Acid- MnO_4	Acid OsO_4	Mixture of the two
Acid	$73.5-74.5^\circ$	$73.5-74.0^\circ$	$73-74^\circ$
Phenylhydrazide	129.5°	129.5°	129.5°
Tolylhydrazide	111.5°	111.5°	111.0°

The freshly-prepared Acid- MnO_4 lost 12.67% of its weight, the Acid- OsO_4 12.82% as water of crystallization; this corresponds to 1 mole.

In a similar way the Acid- OsO_4 and the Acid-HOCl may be compared and shown to have very different properties.

COMPARISON OF MELTING POINTS

Compound	Acid- OsO_4	Acid-HOCl	Mixture of the two
Acid	$73.5-74.0^\circ$	81.5°	$63-74^\circ$
Phenylhydrazide	129.5°	103.0°	$109-122^\circ$
Tolylhydrazide	111.5°	103.0°	$99-105^\circ$

The Acid-HOCl lost only 0.16% in weight in drying to constant weight and hence contained no water of crystallization. The Acid- OsO_4 was noticeably less soluble in cold water than was the Acid-HOCl. This difference in solubility was sufficiently marked to be of practical importance in the recrystallization of the two acids from water.

The salts of the Acid-HOCl and Acid- OsO_4 exhibited marked differences in behavior. The barium salt of the Acid-HOCl could not be crystallized from water; the barium salt of the Acid- OsO_4 , on the other hand, crystallized from hot water as finely matted, glistening needles. The silver salts of Acid-HOCl and Acid- OsO_4 could both be recrystallized from hot water; the salt of the Acid- OsO_4 consisted of large, glistening, silver-white leaves, however, whereas the salt of Acid-HOCl was obtained as a dull white powder.

The hydrazides (both the phenyl and *o*-tolyl) of the Acid- OsO_4 consisted of definite, large crystals which were sparingly soluble in hot absolute alcohol. The hydrazides of the Acid-HOCl were coarse powders which were markedly more soluble in alcohol than were the hydrazides of the other acid.

Summary

This paper is a report (a) of the repetition, with some modifications, of the preparation of the two *dl*-1,2-dihydroxybutyric acids reported by Melikoff and Fittig and Kochs; (b) of the preparation of one of these acids by a new procedure; (c) of the preparation of two new derivatives (phenylhydrazides and *o*-tolylhydrazides) of each of the two acids; (d) of a careful comparative study of the properties of the acids produced by the three procedures and of a few of their derivatives; and (e) of the con-

clusion that the two theoretically possible *dl*-1,2-dihydroxybutyric acids have melting points of 73.5–74.5 and 81.5°.

THE PREPARATION OF TETRAPHENYL LEAD¹

BY HENRY GILMAN AND JACK ROBINSON

RECEIVED JUNE 21, 1927

PUBLISHED SEPTEMBER 2, 1927

There are, at present, two general methods for the preparation of tetraphenyl lead. One, by Polis,² is the protracted heating of an ethyl acetate solution of bromobenzene with sodium-lead alloy. The other, by Pfeiffer and Truskier,³ is commonly represented by the following reaction.⁴

The method using the Grignard reagent has been widely employed⁵ because of its greater convenience and better yields. In connection with the application of organolead compounds as antiknock reagents and in the treatment of cancer and some plant diseases, tetraphenyl lead is being used as one of the types for the preparation of variously substituted derivatives. The present study reports the effect of various factors on the yield of tetraphenyl lead as prepared by the Grignard reaction. Using Pfeiffer and Truskier's technique we have not succeeded in equaling their yields. However, the quantity of phenylmagnesium bromide required to give a yield that closely approximates theirs has been significantly decreased below that which they used. Our present maximum yield of about 50% points strongly to a series of reactions more complex than that illustrated in Reaction (1). Experiments have shown that lead chloride cannot be effectively replaced by lead bromide, lead iodide or lead dioxide in this method of preparation. It is possible that better yields may be realized by treating the phenylmagnesium bromide with zinc chloride prior to the addition of lead chloride. Such a method, involving the intermediate formation of organozinc compounds, has been

¹ A preliminary report was read at the meeting of the Iowa Academy of Sciences held at Iowa City on May 6, 1927.

used in the preparation of some other organometallic compounds. Probably the optimal conditions described here for the preparation of tetraphenyl lead cannot be used without some variations in the preparation of other tetra-aryl lead compounds, for Krause and Schmitz^{6d} have found that the quantity of "unsaturated" organolead compound increases with more complex radicals like that present in *p*-xylylmagnesium bromide.

Experimental Part

The following directions give the optimum yield, and they incorporate the more desirable features suggested by a limited study of several factors.

Phenylmagnesium bromide is prepared in a three-necked flask from 12.15 g. (0.5 mole) of magnesium, 78.5 g. (0.5 mole) of bromobenzene and 200 cc. of anhydrous ether. When the Grignard reagent has been prepared in the customary manner,⁶ there is added 400 cc. of benzene which has been dried by standing for a few days over sodium. To this solution is added, in one lot, 63 g. (0.23 mole) of finely divided lead chloride,⁷ and the mixture is refluxed, while being continuously stirred, for eight hours.

After a short time (during the first 30 minutes) the characteristic blackish precipitate forms and this increases in quantity over the first four hours. At the end of the eight hour period of refluxing, the mixture is cooled, and then hydrolyzed by pouring into iced hydrochloric acid. The whole mixture is filtered through a Büchner funnel, and then the ether-benzene layer is separated from the dilute hydrochloric acid layer. The cake of tetraphenyl lead, lead, etc., is removed from the funnel (for convenience the filter paper may be removed with the filter cake) and transferred to a beaker or an Erlenmeyer flask. Three hundred cc. of benzene is then added to the cake or paste and heated for a minute or two while the benzene solution is boiling. The hot benzene extract is then separated from the sludge and heavier deposit of lead by filtration and decantation through a Büchner funnel.

The filtrate is cooled with tap water to about 20°, and the crystals of tetraphenyl lead that separate are filtered and set aside as one crop of quite pure tetraphenyl lead, melting at 224–225°. The filtrate, consisting essentially of a saturated solution of tetraphenyl lead in benzene, is then added to the original cake or sludge of tetraphenyl lead and lead already once extracted, and the extraction process repeated by heating at the boiling point of the solvent for a minute or two, and then filtering to get the second crop of tetraphenyl lead. This also is quite pure and melts at about 224°.

This process of extraction is twice repeated (making four extractions in all) in order to remove practically all of the tetraphenyl lead. For most purposes the fourth extraction may be omitted, for on cooling to 20° after the fourth extraction very little tetraphenyl lead separates.

The benzene-extraction mother liquors (now of a volume slightly less than 300 cc.) are combined with the ether-benzene layer that was obtained after the hydrolysis of the reaction mixture. The combined solvents are then concentrated to about 100 cc. and, on cooling these liquors, from 6–10 g. of tetraphenyl lead is obtained melting at 224°.

The total yield of tetraphenyl lead obtained in this way is 29 g. or 50%, based on the lead chloride used. It is pure enough for most purposes. Recrystallization from

⁶ Gilman and McCracken, *THIS JOURNAL*, **45**, 2462 (1923). Using the general procedures described in this reference, one can count safely on a 90% yield of phenylmagnesium bromide.

⁷ The lead chloride used in these studies was taken directly from a stock bottle and was neither pulverized nor dried.

hot benzene gives a product melting at 225°. From 1 to 2 g. of tetraphenyl lead is soluble in 100 g. of benzene at about 20°.

Extraction of the cake or paste may be effected by the use of a Soxhlet apparatus or some modification of it. However, this is not necessary for ordinary purposes. Furthermore, the hot benzene extracts may be filtered conveniently through a Büchner funnel, as stated, without the use of a steam funnel.

Several experiments showed that the yield after refluxing for eight hours is better than that after four, six or twelve hours of refluxing.

The ratio of ether to benzene in the directions given above is about 1 to 2. A lower yield is obtained when two volumes of ether are used to one of benzene.⁸ There is practically no change in yield when benzene is replaced by toluene. When the directions of Pfeiffer and Truskier³ were followed (ether alone as the solvent and an excess of phenylmagnesium bromide) the yield was 43% and not 58.5% as reported by them. This yield of 43% was obtained in one run using the exact amounts of materials recommended by them, as well as in another run twice this size but under the same general conditions.

There is no advantage in using a larger quantity of phenylmagnesium bromide than that stipulated. The directions, therefore, effect a significant saving of RMgX compound.³ With the quantities finally recommended there is still a slight excess of phenylmagnesium bromide, as is shown by the color test of Gilman and Schulze⁹ for RMgX compounds.

It was believed that the yield could be improved by adding the lead chloride in several parts over extended intervals. In this way there was the possibility that the lead chloride would not be so coated with the sludge deposit as to impede reaction with phenylmagnesium bromide. However, there was no improvement in yield when the lead chloride was added in 20 g. portions at either 20 or 30 minute intervals, over that realized when all of the lead chloride was added at one time.

Summary

Improved directions are given for the preparation of tetraphenyl lead from lead chloride and phenylmagnesium bromide.

AMES, IOWA

⁸ Richards, King and Hall (Ref. 5 (f)) found that the substitution of *iso*-amyl ether for ethyl ether was not effective. They also reported that benzene gave more satisfactory yields than ethyl ether.

THE REDUCTION OF 2-NITROFLUORENE

BY F. E. CISLAK, I. M. EASTMAN AND J. K. SENIOR

RECEIVED JUNE 24, 1927

PUBLISHED SEPTEMBER 2, 1927

The reduction of 2-nitrofluorene to 2-aminofluorene has been described by both Strasburger¹ and Diels.² Strasburger carried out the reduction in acid solution by the use of tin and hydrochloric acid; Diels obtained almost quantitative results with zinc and calcium chloride under very nearly neutral conditions. In a recent paper by Korczynski, Karlowska and Kierzek³ appears the statement that 2-nitrofluorene may be easily reduced in alkaline medium to azoxyfluorene (hereafter referred to as 2,2'-azoxybisfluorene), which on account of its great insolubility separates from the solution and thus escapes the further action of the reducing agent. We have been able to find no other reference to this compound in the literature. Since we have prepared it, as well as some of its derivatives, we judge it best to report on the results so far obtained, although the work in this field is not yet complete.

2,2'-Azoxybisfluorene (I) may be prepared by the reduction of 2-nitrofluorene with zinc and calcium chloride. The amount of zinc used, however, is only one-tenth of that used by Diels in his preparation of the amine.

The azoxy compound is a bright orange substance, almost insoluble in alcohol and ether, and only slightly soluble in the higher-boiling organic solvents. It is best recrystallized from boiling xylene in which it is soluble to the extent of about three per cent. When thus treated, it separates in rectangular platelets which melt at 279° (corr.).

After the empirical formula and molecular weight of the compound had been determined, its structure was demonstrated by reducing it further to 2-aminofluorene. Because of the insoluble nature of the substance, it was necessary to carry out the reduction under special conditions. When the compound was suspended in alcohol, even prolonged treatment with a large excess of zinc and calcium chloride failed to produce more than a slight change. Zinc and acetic acid were also without effect. Success was finally obtained by taking advantage of the solubility of the azoxy compound in phenol. Zinc dust was added to a warm phenol solution of the substance. Then hydrochloric acid was added, and the

¹ Strasburger, *Ber.*, 17, 108 (1884).² Diels, *Ber.*, 34, 1759 (1901).³ Korczynski, Karlowska and Kierzek, *Bull. soc. chim.* (4), 41, 68 (1927).

mixture warmed until all the zinc had dissolved. The deep blue-green color, which appeared as soon as the hydrochloric acid was added to the phenol solution, was bleached during the reduction, and from the reaction mixture 2-aminofluorene was isolated in an amount corresponding to 82% of the azoxy compound used. This result, together with the analysis and molecular weight, is considered to demonstrate the structure of the substance in question.

Attempts were made to oxidize 2,2'-azoxybisfluorene to the corresponding bisfluorenone by treating it with hot chromacetic acid, but even prolonged boiling with this reagent failed to alter the compound—an unusual result in view of the ease with which most fluorene derivatives are converted to fluorenones under these conditions.

During the reduction of 2,2'-azoxybisfluorene to 2-aminofluorene, there was always formed along with the amine a small amount of a white, difficultly soluble substance which, when recrystallized from xylene, formed hexagonal platelets, melting at 257–258° (corr.). By modifying the method of reduction, this compound could be obtained as the principal reaction product. To prepare it, acetic acid instead of hydrochloric acid was used and the reduction was conducted below 45° with as little acid as possible. The compound was at first supposed to be 2,2'-hydrazobisfluorene (II), a supposition with which its analysis and molecular weight agreed; but the behavior of the substance was incompatible with this assumption. In the first place, it obstinately resisted further reduction with zinc and hydrochloric acid even in phenol solution. Under no conditions could it be converted to 2-aminofluorene. Secondly, the compound, when oxidized, yielded only deeply-colored amorphous products. It was impossible to isolate any substance identifiable as 2,2'-azobisfluorene (III) which ought easily to be formed if the compound had the supposed structure.

The most probable alternative hypothesis is that the hydrazo compound really was formed in the course of the reduction, but that, under the influence of the acetic acid, it underwent one of the molecular rearrangements characteristic of compounds of this class. Acetic acid is not a common reagent for producing such rearrangements, but instances of its use for this purpose are known.⁴

Of the five different forms of rearrangement which have been observed⁵

⁴ (a) Meisenheimer, *Ber.*, 36, 4150 (1903). (b) Sachs and Whittaker, *Ber.*, 35, 1433 (1902). (c) Rasso and Rülke, *J. prakt. Chem.* (2) 65, 97 (1902).

⁵ Jacobson, *Ann.*, 428, 81 (1922).

among hydrazo compounds, the benzidine, *p*-semidine, and *o-p*-diphenyloid forms are inapplicable to the present case, because the positions *para* to the hydrazo group are occupied by the bond between the six-membered rings of the fluorene. The remaining two rearrangements (*o-o*-diphenyloid and *o*-semidine) might lead to five different compounds, all isomeric with 2,2'-hydrazobisfluorene.

It was possible to eliminate some of these possibilities by acetylating the compound in question. When treated with acetic anhydride it readily yielded a white derivative which crystallized from xylene in needles melting at 179° (corr.). This compound contained no oxygen and showed by analysis the presence of two more atoms of carbon per molecule than the parent compound. The only simple explanation of these facts is that the acetylated derivative is a C-methyl imidazole. If such is the case, the two nitrogen atoms in the unacetylated compound must occupy two adjacent positions on one phenyl ring, both of them must be amine nitrogens and at least one of them must be primary. Such a configuration is the result of a rearrangement of the *o*-semidine type.

The rearrangement together with the subsequent imidazole formation may be represented by one of the two following schemes.

The two compounds are either 2'-amino-2,3'-difluorylamine (IV) and 3-(2-fluoryl)-2-methyl-2,3-fluorenimidazole (V), respectively, or else they are, respectively, 2-amino-1,2'-difluorylamine (VI) and 1-(2-fluoryl)-2-methyl-2,1-fluorenimidazole (VII). At present, there exist no data which would permit a choice between these two possibilities.

The only property of the unacetylated compound (IV or VI) which is

not in harmony with this interpretation is its weak basic nature. If it does contain a primary amine group it ought to form salts. None such could, however, be obtained in aqueous solution. It is probable that the heavy aryl radicals and extreme insolubility of the substance greatly weaken its basic properties.

Other methods of reducing 2-nitrofluorene were also tried. When boiled in aqueous alcoholic solution with ammonium sulfide, it was not altered. This result is rather curious since the reagent used is very effective in reducing the corresponding 2-nitrofluorenone. When 2-nitrofluorene is treated in methyl alcohol solution with sodium methylate, it yields a brown product which has not yet been fully investigated. It is hoped to identify this substance as well as to find methods of preparing the hydrazo and azo compounds (II and III) which have as yet escaped detection.

Experimental Part

Preparation of 2,2'-Azoxybisfluorene.—2-Nitrofluorene (30 g.) was suspended in one liter of boiling aqueous alcohol (sp. gr. 0.87) to which a solution of 10 g. of calcium chloride in 15 cc. of water had been added. Zinc dust (30 g.) was then added and the mixture refluxed for two hours, cooled and filtered. The cloudy filtrate was then evaporated to small volume and again filtered. The combined precipitates were dried in an oven at 100°. The dried material was treated with about 1500 cc. of boiling xylene, and the hot solution filtered to free it from suspended excess zinc. When the xylene solution was cooled, 2,2-azoxybisfluorene separated in orange-yellow, rectangular plates. The first yield was about 15 g. and an additional 5 g. could be obtained by concentrating the mother liquor. After two recrystallizations from xylene, the substance melted with decomposition at 279° (corr.).

Anal. Calcd. for $C_{26}H_{18}N_2O$: N, 7.49; C, 83.38; H, 4.85. Found: 7.24, 7.45; 83.14, 83.05; 5.10, 5.08.

The molecular weight was determined by the camphor method of Rast.*

Mol. Wt. Calcd. for $C_{26}H_{18}N_2O$: 374. Found: 411, 404, 417.

Reduction of 2,2-Azoxybisfluorene to 2-Aminofluorene.—2,2-Azoxybisfluorene (2 g.) was dissolved in 25 cc. of warm phenol to which zinc dust (5 g.) had been added. Strong hydrochloric acid (20 cc.) was added in small amounts while the mixture was warmed on a hot-plate. By the time the zinc had all dissolved, the deep blue-green color formed when the acid was first added had almost entirely vanished. The entire reaction mixture was poured into water, and sodium hydroxide added in large enough excess to dissolve the zinc hydroxide formed. The insoluble precipitate was removed by filtration and dissolved in alcohol. The filtered solution was poured into excess water and the precipitate removed by filtration. When dried, it weighed 1.65 g., and was identified as 2-aminofluorene. It melted at 124°, and the melting point of a mixture of the compound with 2-aminofluorene (m. p. 129°) was 127°.

The Reduction and Subsequent Ortho-semidine Rearrangement of 2,2-Azoxybisfluorene.—2,2-Azoxybisfluorene (5 g.) was dissolved in 60 cc. of hot phenol. Zinc dust (10 g.) was added and the mixture cooled to 40° while constantly agitated. The azoxy compound separated as a thick paste. Glacial acetic acid (1.75 cc.) was added, a few drops at a time, in the course of about 15 minutes, during which time the mixture

* Rast, *Ber.*, 55, 1051 (1922).

was kept well stirred. The temperature was held below 45°. As the reduction proceeded, the mass became more fluid, and the end of the reaction was marked by the disappearance of the yellow color. The entire reaction mixture was then poured into 1200 cc. of water. The rather oily precipitate became granular when stirred. It was removed by filtration and suspended in 100 cc. of warm alcohol. It was again collected on a filter and then treated with 200 cc. of boiling xylene. The hot xylene solution was filtered to remove excess zinc. When the filtrate was cooled, it deposited a grayish substance, crystallizing in irregular hexagonal scales. This was the substance IV or VI.

As thus prepared the compound contained colored impurities very difficult to remove by recrystallization. It was best purified by dissolving it once more in phenol and treating it with zinc and hydrochloric acid. From the reaction mixture the compound was isolated in the manner already described. After two recrystallizations from xylene, it was obtained in the form of white crystals which, when moist, tended to darken on exposure to the air. The dried compound turned red at 240–245° and melted with decomposition at 257–258° (corr.). The yield was about 50%. The substance is only very slightly soluble in alcohol and ether. It may be recrystallized by adding alcohol to a warm nitrobenzene solution.

Anal. Calcd. for $C_{28}H_{20}N_2$: N, 7.78; C, 86.62; H, 5.60. Found: 7.69, 7.53, 86.85, 86.75, 5.91, 5.84.

The molecular weight was determined by the camphor method.

Mol. Wt. Calcd. for $C_{28}H_{20}N_2$: 360. Found: 312, 330.

Preparation of Compound V or VII.—Compound IV or VI (3 g.) was boiled for two hours with 15 cc. of acetic anhydride. When the cooled reaction mixture was poured into 40 cc. of alcohol, a paste of needle-shaped crystals formed. When dried these melted at 146°. Two recrystallizations from xylene raised the melting point to 179° (corr.), where it remained constant on further recrystallization. The yield was about 65%. The substance is fairly soluble in alcohol, benzene and acetone.

Anal. Calcd. for $C_{28}H_{20}N_2$: N, 7.29; C, 87.45; H, 5.25. Found: 7.26, 7.30, 87.33, 87.83, 5.66.

The molecular weight was determined cryoscopically in benzene.

Mol. Wt. Calcd. for $C_{28}H_{20}N_2$: 364. Found: 437, 438, 438.

Summary

The preparation and properties of 2,2'-azoxybisfluorene are described. This substance may be reduced, but at the same time it undergoes a rearrangement of the *o*-semidine type. The substituted orthodiamine thus formed readily yields an imidazole derivative.

THE MECHANISM OF THE REACTION BETWEEN LITHIUM *N*-BUTYL AND VARIOUS ORGANIC HALOGEN COMPOUNDS

BY C. S. MARVEL, F. D. HAGER AND D. D. COFFMAN

RECEIVED JULY 7, 1927

PUBLISHED SEPTEMBER 2, 1927

The lithium alkyls are reagents that have not been widely used and many of their reactions have not been thoroughly investigated. It is known that they are spontaneously inflammable in air; that they react with almost any type of organic compound containing oxygen;¹ that they react with water to give the hydrocarbon;² and that they react with quarternary ammonium halides.³ It seemed likely that they might be used to advantage in the synthesis of hydrocarbons by allowing them to react with various halogen derivatives of hydrocarbons. The simple reaction that might be expected would be $RX + LiR' \longrightarrow RR' + LiX$.

In investigating the possibilities of this reaction, lithium *n*-butyl was chosen as a typical lithium alkyl because it is comparatively easy to prepare and is quite soluble in petroleum ether. The lithium *n*-butyl solution was prepared in a large reaction flask, measured, analyzed and then transferred to smaller graduated flasks so that a known amount could be used in each reaction. The halogen compound, usually in solution or suspension in purified petroleum ether, was mixed with the lithium *n*-butyl solution in sealed tubes in such a way that no air was admitted.

The reaction between lithium *n*-butyl and the following halogen compounds was studied: *n*-heptyl bromide, trimethylene bromide, methylene iodide, carbon tetrachloride, β -bromostyrene, tetrachloro-ethylene, *o*-, *m*- and *p*-bromotoluenes, *o*-dichlorobenzene, hexabromobenzene, α -chloropyridine and triphenylchloromethane. With *n*-heptyl bromide, methylene iodide, β -bromostyrene, *p*-bromotoluene and triphenylchloromethane some of the expected hydrocarbon was isolated in each case but the yields varied over a wide range. The other halogen compounds in general gave unexpected compounds or tarry products from which nothing definite could be isolated.

It was noticed in nearly every case that a marked color developed when the lithium *n*-butyl solution and the halogen compound were mixed: This color usually disappeared if the mixture was allowed to stand for several days. The development of color was particularly noticeable when β -bromostyrene was used. When it was first treated with lithium *n*-butyl solution a deep red color appeared. This color changed to a purple and then gradually faded out entirely. When this tube was opened,

¹ Schlenk and Holtz, *Ber.*, 50, 271 (1917).

² Grosse, *Ber.*, 59, 2653 (1926).

³ Hager with Marvel, *THIS JOURNAL*, 48, 269 (1926).

the products isolated from the reaction were phenyl-1-hexene-1 and *trans-trans*-diphenyl-1,4-butadiene-1,3.

The production of color and the isolation of diphenylbutadiene suggested that probably the reaction between lithium *n*-butyl and β -bromostyrene gave first two free radicals, the *n*-butyl radical and the group $C_6H_5CH=CH-$. These free radicals could then react subsequently in the following manners.

The products isolated indicate that reactions I and III actually had taken place. Probably reaction IV also occurs and the butyl group is lost as gaseous butene-1 and butane. There is no indication that either octane, phenylethylene or phenylacetylene was produced.

If the reaction really proceeds through the formation of free radicals, it would be expected that if lithium *n*-butyl were allowed to react with triphenylchloromethane, the characteristic color of triphenylmethyl would appear. When this reaction was carried out a highly colored solution was obtained. The color deepened on heating the mixture and faded on cooling as it should if hexaphenylethane were produced. When the reaction vessel was opened the color was discharged. The products isolated from the reaction mixture were triphenyl-1,1,1-pentane, triphenylcarbinol and *n*-butyl alcohol. The triphenylcarbinol was a secondary product obtained by the action of sulfuric acid on a mixture of the hydrocarbon and some sulfuric acid soluble product which could not be isolated by crystallization from inert solvents. This substance was presumably triphenylmethylperoxide, the presence of which indicates that a reaction analogous to II above occurred to give hexaphenylethane, which was then oxidized in the air, when the tube was opened, to give the peroxide. The *n*-butyl alcohol must have been formed from a smaller amount of unreacted lithium *n*-butyl by oxidation with air.

The formation of very complex products from compounds containing more than one halogen would be predicted if free radicals are intermediate products in this reaction. Of the polyhalogen compounds studied, only methylene iodide gave enough of the expected hydrocarbon for isolation, and a large high-boiling portion was produced as a side product. *o*-Dichlorobenzene and hexabromobenzene gave very complex insoluble compounds. Trimethylene bromide and carbon tetrachloride gave high-

boiling products from which no definite pure substances could be isolated. Tetrachloro-ethylene was used in only one reaction and when it was mixed with the lithium *n*-butyl solution a very violent explosion occurred.

The only halogen compound used which was not a hydrocarbon derivative was α -chloropyridine. It gave a very tarry product from which nothing definite could be isolated. A free radical of the type  would not be

expected to be very stable.

The products isolated from the reaction of lithium *n*-butyl and *o*-, *m*- and *p*-bromotoluene were the most unexpected. *p*-Bromotoluene and lithium *n*-butyl gave a 76% yield of *p*-*n*-butyltoluene. On the other hand *o*- and *m*-bromotoluenes gave nearly quantitative yields of toluene. In the case of *p*-bromotoluene the reaction is almost entirely of the type illustrated by Equation I. With the *ortho* and *meta* isomers the reaction is almost entirely of the type illustrated by Equation VI. This difference in reaction between *ortho*, *meta* and *para* isomers would not be predicted.

While no butene or butane has been isolated from any of the reaction mixtures, as would be required to establish definitely the exact course of the reaction, there seems to be little doubt that free radicals are first produced when a halogen compound reacts with a lithium alkyl. A very similar mechanism for the Wurtz-Fitting reaction for the synthesis of hydrocarbons has been recently advanced by Bachmann and Clarke.⁴

Experimental Part

Apparatus and General Procedure.—About 1 liter of 1 molar lithium *n*-butyl solution in petroleum ether was prepared and analyzed according to the procedure of Hager and Marvel³ and then transferred from the reservoir C to a series of small reaction flasks as shown in Fig. 1. The reaction flasks were made in two compartments, separated by a glass valve easily broken. In one (D) the lithium *n*-butyl solution was measured. In the other compartment (E) was placed the halogen compound dissolved or suspended in purified petroleum ether. The compartment containing the lithium *n*-butyl solution was sealed off, the glass valve between the two compartments was broken and the two solutions were slowly mixed. In order to avoid accidents the reaction flask was placed behind a heavy glass shield before the valve was broken.

Fig. 1.

⁴ Paper presented before the Organic Section of the American Chemical Society at the meeting in Richmond, April, 1927, *THIS JOURNAL*, 49, 2089 (1927).

The petroleum ether was purified as described in the earlier paper.⁵ The fraction boiling at 35–50° was used. Air was removed from the reaction flasks by displacement with solvent vapors or by evacuating the flask with a mercury vapor pump. All of the liquid halogen compounds were purified by distillation and the material used boiled over only a one-half degree range in most cases. The solid halogen compounds were recrystallized until their melting points were constant.

After the reactions were complete, the reaction flasks were opened and the contents poured into ice water. The aqueous solution was saved and analyzed for halogen and for alkalinity. This gave a rough check on the completeness of the reaction. In nearly every case the reactions ran to completion as far as removal of halogen was concerned. The petroleum ether solutions were carefully distilled and the higher-boiling residues of hydrocarbons were separated as far as possible by distillation or crystallization.

The reaction between lithium *n*-butyl and triphenylchloromethane was carried out in the apparatus shown in Fig. 2. This change in style of apparatus seemed desirable because of the low solubility of the halogen compound in low-boiling petroleum ether. The lithium alkyl solution was placed in one bulb (A) and the dry triphenylchloromethane in the other (B). Some of the petroleum ether was then distilled over into the bulb containing the halogen compound. Some of the triphenylchloromethane dissolved. The apparatus was tilted and this solution was filtered into the lithium *n*-butyl solution. These processes were repeated until all of the triphenylchloromethane was carried into the bulb containing the lithium *n*-butyl.

Fig. 2.

Lithium *n*-Butyl and *n*-Heptyl Bromide.—Approximately 0.25 mole of lithium *n*-butyl was mixed with 0.25 mole of *n*-heptyl bromide. After 90 days the tube was opened and the contents poured into ice water. Careful fractionation of the petroleum ether layer resulted in the isolation of 4 g. of nearly pure *n*-undecane. The observed constants were, b. p. 192–197°; d_4^{20} 0.7966, n_D^{22} 1.4220. The constants reported in the literature⁶ are: b. p. 195°; d_4^{20} 0.741; n_D^{20} 1.4184.

Lithium *n*-Butyl and Methylene Iodide.—This reaction was run with 0.50 mole of lithium *n*-butyl and 0.25 mole of methylene iodide. The reaction mixture stood for 23 days before it was opened. About 2 g. of impure *n*-nonane was isolated from a considerable quantity of higher-boiling material which could not be separated into definite fractions. The observed physical constants were: b. p. 147–149°; d_4^{20} 0.7486; n_D^{18} 1.412; whereas those given in the literature⁶ are: b. p. 150.6°; d_4^{20} 0.718; n_D^{20} 1.405.

Lithium *n*-Butyl and β -Bromostyrene.—The reaction was run with 0.25 mole of each reagent. The reaction mixture stood for 38 days before opening. The petroleum ether was distilled under ordinary pressure and then a fraction was removed under

⁵ International Critical Tables, Vol. I. McGraw-Hill Book Co., 1926, page 243.

⁶ Ref. 5, p. 230.

reduced pressure. The residue solidified. The fraction which was distilled under reduced pressure had the following physical constants: b. p. 97–100° at 8 mm.; d_4^{25} 0.9455; n_D^{25} 1.5377; M_p calcd. for phenyl-1-hexene-1, 53.55; found, 52.96.

Anal. (total carbon). Subs. 0.4123: 809.1 cc. CO₂ at 26° and 738.4 mm. Calcd. for C₁₂H₁₄: C, 89.93. Found: 89.65.

The solid residue in the distilling flask was recrystallized from ethyl alcohol and then melted at 145–146°. It added bromine readily to give a product which melted with decomposition at 235–242°. The *trans-trans* isomer of diphenyl-1,4-butadiene-1,3 melts at 147–148° and adds bromine to give a tetrabromo addition product which melts with decomposition at 230°.⁷

Lithium *n*-Butyl and Triphenylchloromethane.—The reaction was run for 9 days using 0.20 mole of triphenylchloromethane and 0.23 mole of lithium *n*-butyl. In working up the product some material crystallized from the petroleum ether. This was separated and found to consist of more than one substance. On treatment with sulfuric acid part of the material went into solution. This was poured into ice water and a solid separated. On recrystallization from alcohol pure triphenylcarbinol melting at 160–161° was obtained. Since the original material would not give triphenylcarbinol on recrystallization alone, this must have been produced from triphenylmethyl peroxide by the action of sulfuric acid.

On distilling the petroleum ether about half a gram of material boiling at 105–116° with the characteristic odor of *n*-butyl alcohol was isolated. Its identification as *n*-butyl alcohol was confirmed by making the 3,5-dinitrobenzoate, which melted at 61°.

The residue after removal of the petroleum ether and *n*-butyl alcohol was distilled under 0.01 mm. pressure and a fraction boiling at 170–180° was isolated. After a few days this fraction solidified and on recrystallization from petroleum ether, acetone or ethyl alcohol gave crystals melting at 153–154°.

Anal. Subs. 0.1642, 0.1680: CO₂, 0.5536, 0.5649; H₂O, 0.1230, 0.1225. Calcd for C₂₂H₂₄: C, 91.94, H, 8.06. Found: C, 92.09, 91.73; H, 8.39, 8.16.

This material is undoubtedly triphenyl-1,1,1-pentane. The total amount isolated was 16 g., or about 26% of the calculated amount.

Lithium *n*-Butyl and α -Chloropyridine.—The quantities used in this experiment were 0.35 mole of lithium *n*-butyl and 0.30 mole of α -chloropyridine. The reaction mixture stood for 7 days. Only tarry, insoluble products could be isolated.

Lithium *n*-Butyl and *o*-Bromotoluene.—A mixture of 0.25 mole of *o*-bromotoluene and 0.27 mole of lithium *n*-butyl was allowed to stand for 4 days. On fractionation of the petroleum ether a 65% yield of toluene boiling at 109–113° was isolated. It was further identified by oxidation to benzoic acid, m. p. 121°, and nitration to 2,4-dinitrotoluene, m. p. 70–71°.

Lithium *n*-Butyl and *m*-Bromotoluene.—A mixture of 0.24 mole of *m*-bromotoluene and 0.25 mole of lithium *n*-butyl was allowed to stand for 4 days. An 87% yield of toluene was isolated.

Lithium *n*-Butyl and *p*-Bromotoluene.—A mixture of 0.25 mole of each reagent was allowed to stand for 30 days. From the petroleum ether was obtained 28 g. (75% of the calculated amount) of *p*-butyltoluene, b. p. 197–200°; n_D^{14} 1.5009; d_4^{14} 0.9452. The constants given in the literature⁸ are: b. p. 198–199°; d_4^{14} 0.8618; n_D^{14} 1.4912. Since the constants did not check as closely as might be desirable, a sample of the hydrocarbon was oxidized to terephthalic acid and this then converted to the dimethyl ester, which melted at 137–138°.

⁷ Rebuffat, *Gazz. chim. Ital.*, 15, 107 (1885); 20, 155 (1890).

⁸ Niemczycki, *Chem. Zentr.*, 71, 468 (1900).

Lithium *n*-Butyl and Polyhalogen Compounds.—When lithium *n*-butyl solutions were allowed to react with trimethylene bromide and carbon tetrachloride, complex liquid hydrocarbon mixtures were obtained. With *o*-dichlorobenzene heavy, tarry products slightly fluorescent in solution were produced. Hexabromobenzene gave a dark insoluble powder. A similar powder was obtained when lithium phenyl was used instead of lithium *n*-butyl. When tetrachloro-ethylene was used a violent explosion occurred.

Summary

1. The reaction between lithium *n*-butyl and various halogen compounds has been studied.
2. In general the simple reaction of replacement of halogen by the *n*-butyl group does not occur.
3. The products which were formed suggest that the first step in the reaction of lithium *n*-butyl and a halogen compound is the formation of free radicals. These then undergo further reactions which differ widely for different groups.

MAGNESIUM DIETHYL AND ITS REACTION WITH ACETYL CHLORIDE

BY HENRY GILMAN AND F. SCHULZE

RECEIVED JULY 18, 1927

PUBLISHED SEPTEMBER 2, 1927

Introduction

Magnesium diethyl was apparently first prepared by Hallwachs and Schafarik¹ by heating magnesium with ethyl iodide. They described it as a solid, although the reactions of the liquid or oily fraction indicate that some magnesium diethyl was contained in the excess ethyl iodide. Later, Cahours² carried out the preparation from the same materials but he described his product as a liquid. Löhr³ then prepared magnesium diethyl by heating magnesium with ethyl iodide and also by heating magnesium with mercury diethyl. His product was a solid. Fleck⁴ extended Löhr's work on magnesium dialkyls, and, among other reactions, made a careful study of the reaction between magnesium diethyl and acetyl chloride.

We have prepared magnesium diethyl by the preferred method of Löhr³ and Fleck,⁴ namely, by heating magnesium with mercury diethyl

¹ Hallwachs and Schafarik, *Ann.*, 109, 206 (1859).

² Cahours, *Ann.*, 114, 227 (1860).

³ Löhr, *Ann.*, 261, 48 (1891).

⁴ Fleck, *Ann.*, 276, 129 (1893).

in a sealed tube. However, we had no success in a few experiments even when Löhr's directions were carefully followed until a very small amount of mercuric chloride was used as a catalyst.⁵ The magnesium diethyl so obtained was a solid and not a liquid.

Fleck⁴ obtained trimethylcarbinol from the reaction between magnesium *dimethyl* and acetyl chloride. This is exactly as one would expect. However, he got the same carbinol from magnesium *diethyl* and acetyl chloride. This is certainly what one would not expect. Fleck did not expect to get this compound; instead he looked for dimethylethylcarbinol. He was quite aware of the apparently abnormal course of his reaction between magnesium diethyl and acetyl chloride; but there was no doubt in his mind because the product from magnesium diethyl was identical with that from magnesium dimethyl. He repeated the reaction between magnesium diethyl and acetyl chloride several times, and finally "left this quite striking observation unexplained."

In our work with beryllium alkyls, acetyl chloride was used as one of the reagents and it gave the normal or expected products. The same is true with magnesium diethyl, for it has been shown that dimethylethylcarbinol and not trimethylcarbinol is obtained from magnesium diethyl and acetyl chloride.

Experimental Part

It was not found possible to prepare magnesium diethyl by heating magnesium powder with mercury diethyl in an evacuated sealed tube at 130°, even when the heating was continued for 3 days. At a somewhat higher temperature, about 150°, the tube exploded after a short period of heating. However, when fresh mercury diethyl and a small amount of mercuric chloride were heated with magnesium powder at 130° a reaction set in at once. The reaction product was a light gray or brown powder, spontaneously inflammable in the air. On opening the reaction tube there was considerable pressure.

The material was removed from the tubes by dissolving it in 50 cc. of ether. The ether solutions gave a strong positive color test⁶ for reactive organometallic compounds, a test not shown by mercury diethyl. A violent reaction took place when an ether solution of acetyl chloride was added to the magnesium diethyl in ether.⁷ When a negative color test⁶

⁵ The same catalyst has given decidedly successful results in the preparation of organoberyllium compounds. Also, it has been used to bring about reaction between magnesium and some RX compounds that react very slowly with magnesium in ether. Mention of this catalyst, as well as many others, was made in a preliminary paper presented by Gilman, Schulze and Peterson at the Philadelphia, 1926, meeting of the American Chemical Society. The paper has been submitted for publication.

⁶ Gilman and Schulze, *THIS JOURNAL*, 47, 2002 (1925).

⁷ There is no apparent heat of reaction or heat of solution when anhydrous ether is added to magnesium diethyl.

was given (showing that an excess of acetyl chloride was present) the mixture was hydrolyzed by pouring it onto cracked ice containing a small amount of hydrochloric acid. On working up the extract in the customary manner by removing the ether, there remained a liquid with a pronounced camphor-like odor. This distilled between 120 and 125°, with the last portion coming over at about 130°. In order to further characterize this water-insoluble carbinol, it was converted to the corresponding chloride by passing in hydrogen chloride until no more of this gas was absorbed. The methyldiethylchloromethane when distilled in a micro-distillation flask boiled at 115–118°. Its refractive index was 1.4037.

An authentic specimen of methyldiethylcarbinol was prepared from methyl ethyl ketone and ethylmagnesium bromide. It boiled at 120–122°. Treatment with hydrogen chloride gave the methyldiethylchloromethane boiling at 115–118°, and having a refractive index of 1.4034 as determined under the same conditions used for the unknown chloride.

The similarity of the carbinols and the chlorides obtained from them leaves no doubt as to the formation of methyldiethylcarbinol from magnesium diethyl and acetyl chloride.

Summary

Magnesium diethyl prepared by heating magnesium powder with mercury diethyl in the presence of mercuric chloride as a catalyst is a solid and not a liquid. When treated with acetyl chloride it gives methyldiethylcarbinol and not trimethylcarbinol as previously reported.

A NEW PROCEDURE FOR THE QUANTITATIVE ESTIMATION OF SELENIUM IN ORGANIC COMPOUNDS

BY EDWIN H. SHAW, JR., AND E. EMMET REID

RECEIVED AUGUST 8, 1927

PUBLISHED SEPTEMBER 2, 1927

Introduction

During the recent investigation of some organic selenium compounds the authors¹ felt the need of a simple and direct method of estimating selenium. Most of the methods described in the literature depend on a Carius tube combustion which is slow and tedious. As combustion with sodium peroxide in the Parr bomb has been so successful with sulfur,² and has supplanted the Carius method with halogens,³ it seemed advisable to adapt this method to the determination of selenium. The only novelty is in the use of the fusion method. Two commonly used methods have

¹ Shaw and Reid, *THIS JOURNAL*, **43**, 320 (1923).

² Parr, *ibid.*, **30**, 763 (1906).

³ Lemp and Broderick, *ibid.*, **39**, 2069 (1917).

been employed for the determination of the selenium in the solution of the melt.

Historical

Siemens⁴ determined selenium in ethyl selenomercaptan by passing its vapors over hot copper oxide and noting the change in weight, $\text{CuO} \rightarrow \text{CuSe}$. Michaelis and Röhmer⁵ heat the compound in a bomb tube with fuming nitric acid, reflux the product with excess hydrochloric acid to remove the nitric acid, and precipitate elementary selenium from the resultant solution with sodium sulfite. Bauer⁶ describes a similar process. Lyons and Shinn⁷ modify the elimination of the nitric acid by evaporating the solution to dryness with the addition of silver nitrate or zinc nitrate to prevent loss of selenious acid. The product is dissolved in dilute hydrochloric acid, and either titrated with thiosulfate or precipitated with sodium sulfite. Frerichs⁸ oxidizes in the same way but converts the selenium into silver selenite, and determines silver volumetrically as a measure of the selenium present, while Becker and Meyer⁹ weigh the silver selenite formed. Wrede¹⁰ burns the compound in oxygen in the presence of platinum as a catalyst, and titrates the selenious acid formed with centi-normal sodium hydroxide, sodium acid selenite being neutral to methyl orange.

Results

The procedure which was arrived at after many variations of the conditions, and which gave satisfactory results with all the compounds tried, was as follows. Mix the weighed sample, 0.2 to 0.4 g., with 0.4 g. of cane sugar, 0.2 g. of potassium nitrate and 14 g. of sodium peroxide and spread a thin blanket of sodium peroxide over the charge. The combustion is made in the usual manner. The melt is dissolved in water, boiled to destroy hydrogen peroxide, cooled, acidified with hydrochloric acid, filtered and diluted to 350 cc. The selenium in this solution is in the form of selenic acid, and is not reduced to the free elementary form by passing sulfur dioxide through the solution. From this solution the selenium may be precipitated by two alternative methods.

1. **Precipitation by Sulfur Dioxide.**—The sulfur dioxide precipitation was first described by Rose.¹¹ This method has the advantage of rapid and complete precipitation, and the disadvantage of possible loss of the

volatile selenium monochloride from the hot solution.¹³ This loss can be reduced by shortening the time of heating the selenic acid with excess hydrochloric acid and by using a rapid stream of sulfur dioxide to bring about the reduction. To the 350 cc. of solution obtained above, 200 cc. of concentrated hydrochloric acid is added, and the solution covered with a watch glass and brought to the boiling point. Sulfur dioxide is passed into the hot, but not boiling, solution until the precipitate has entirely coagulated and the supernatant liquid is clear. The watch glass is rinsed into the solution and 200 cc. of water are added to the solution. The precipitated selenium is filtered through a Gooch crucible, the beaker is rinsed with alcohol to remove traces of adhering selenium and the precipitate is washed with alcohol and finally several times with water. The Gooch crucible is dried at 110–120° and weighed.

2. **Precipitation by Potassium Iodide.**—The potassium iodide precipitation has been described by Peirce.¹³ By this method the reduction of selenates is not complete unless all the iodine is boiled out of the solution, and in the presence of excess iodine some of it is strongly adsorbed by the selenium. The continued boiling of the solution to expel the iodine may lead to mechanical loss of selenium. Care to prevent too vigorous boiling will prevent this mechanical loss. To the 350 cc. of solution obtained above, 50 cc. of concentrated hydrochloric acid is added and 3 g. of potassium iodide. Boil the solution gently to remove the iodine, replacing the water lost by evaporation. This boiling out requires about two hours. The selenium is then filtered through a Gooch crucible, the beaker is rinsed with alcohol to remove traces of adhering selenium and the precipitate is washed with alcohol and finally several times with water. The Gooch crucible is dried at 110–120° and weighed.

Experimental

The organic selenium compounds used to demonstrate this analytical method are described in a previous paper by the authors.¹ Another compound was used, *p*-nitrophenylselenocyanate prepared by the method of Bauer.¹⁴ As described by Bauer, the compound is not pure, being colored light brown and melting at 136.7–137.3° (corr.). The product can be purified by dissolving in concentrated nitric acid and precipitating by the addition of water. It crystallizes in thin leaves, has a very slight yellowish color and melts sharply at 139.4° (corr.). An additional recrystallization by dissolving in concentrated nitric acid and adding water did not increase the melting point, the product melting simultaneously with the original material at 139.4° (corr.). Recrystallization from water,

in which the compound is sparingly soluble, produced no improvement, the product melting at 139.4° (corr.).

Table I gives results obtained in the analysis of ethyl seleninic acid hydronitrate and *p*-nitrophenylselenocyanate by means of the sulfur dioxide precipitation described above.

Acknowledgment

The authors wish to acknowledge their indebtedness to the late Professor Victor Lenher of the University of Wisconsin and to Dr. S. J. Dickinson of the American Smelting and Refining Company for valuable suggestions as to the precipitation of selenium from selenates by the potassium iodide method.

Summary

The Parr bomb fusion method has been adapted to the analysis of organic selenium compounds. The conditions for the precipitation of the selenium from the solution of the melt have been worked out.

BALTIMORE, MARYLAND

NOTES

The Formation of 1,2-Dichloro-anthraquinone and 2,3-Dichloro-anthraquinone from *o*-Dichlorobenzene.—Phillips states¹ that dichlorobenzoylbenzoic acid of the constitution shown in Formula I does not give

any 1,2-dichloro-anthraquinone on condensation with concentrated sulfuric acid. This statement is erroneous as I have shown² that there is always formed about 13% of 1,2-dichloro-anthraquinone, which remains in the sulfuric acid after the condensation and crystallizes on diluting the acid in little leaflets. The substance melts, contrary to the statement of Ullmann,⁴ at 196.5° (corr.), and not at 207°.

I may add that Phillips' observations are, on the other hand, quite in agreement with ours.³ The 1,2-dichlorobenzene was quite pure, being especially made for us by the Aktiengesellschaft für Aniline Fabrikation in Berlin. I have already published this fact on page 488 of my "Künstliche Organische Farbstoffe" (Berlin, 1926). The yield of the 3',4'-dichlorobenzoylbenzoic acid was in our best experiments 35%.⁵

⁴ See Ullmann, *Encyklopaedia*.

⁵ Ref. 3, p. 29.

Note.—The work of Emil Senn upon which Professor Fierz-David bases his objection to a statement which occurs in my paper (THIS JOURNAL, 49, 473 (1927)) unfortunately was never published in any chemical journal, nor have I been able to find any reference to it or abstract of it in *Chemical Abstracts*, *Chemisches Zentralblatt* or in the *British Chemical Abstracts*. I learned of this work quite recently and have since carried out the condensation of 3',4'-dichloro-2-benzoylbenzoic acid according to the directions given in Senn's dissertation and succeeded in obtaining 4% of the total yield of 1,2-dichloro-anthraquinone. The inference that one might draw from the statement in my paper that no 1,2-dichloro-anthraquinone is formed in this condensation is therefore incorrect and I wish to correct it accordingly. I may add, finally, that in my experiments the yield of 3',4'-dichloro-2-benzoylbenzoic acid was invariably 70% or better.

NEW BOOKS

General Inorganic Chemistry. By M. CANNON SNEED, Professor of Chemistry, University of Minnesota. Ginn and Company, 15 Ashburton Place, Boston, 1926. vi + 674 pp. 132 figs. 21.5 × 14.5 cm. Price, \$3.00.

In this textbook, written for students beginning a college course in chemistry, descriptive and theoretical matter are well balanced, probably more so in the first thirty-one chapters than in the remaining fifteen, which are given over largely to descriptive matter on the metals; but in this latter part we find special coördinating chapters on "Ionic Equilibria," "Colloids," "Chemistry in Living Processes" (written by R. A. Gortner), "Electrochemistry" and "Radioactivity." In arrangement and method of presentation, the author has followed a conservative course. Modern theories and recent industrial applications, however, have not been neglected. The structure of the atom is adequately presented in the splendid chapter on "The Periodic System," and the electron concept as applied to chemical changes is clearly and fully illustrated by well-chosen examples in the chapter on "Oxidation and Reduction."

The style is clear; fundamentals are emphasized by a judicious use of heavy type; misprints and mistakes are very rare; the format is of high standard; most of the diagrams of apparatus show complete set-ups; the illustrations include twelve full-page portraits of noted chemists; the historical matter interspersed adds interest and introduces the human element; nearly every chapter is closed with a limited but well-chosen set of questions and exercises of the type which require careful thought and induce discussion in class conferences; a serious, scientific tone

pervades the book; it deserves rank in the group of up-to-date and scholarly texts for first-year work in general chemistry—new and revised—which have appeared within the past three years.

Other distinctive and valuable features are: A model study outline at the end of Chapter II, "Oxygen and Ozone," helpful both to student and instructor. Much information for reference use is incorporated in the 67 tables, for example, Clarke's full table showing abundance of common elements, p. 17; activity of metals, p. 50; critical temperatures and pressures, p. 107; solubilities of some inorganic substances, p. 197; types of organic compounds, p. 424; composition of alloys (3 tables); silicic acids and their salts, p. 431; constants of metals, pp. 442–443; etc. The chemical equation and heat changes are illustrated in the chapter on "Thermochemistry."

Small volumes are expressed in ml. and not cc. As new terms in elementary texts we note: reactants, dissociants, electrovalence, covalence, monosilane, disilane, electrodialysis, heterocyclic compounds. The millimicron is defined correctly, p. 554, but is designated by the symbol for the micromicron. The use of exact atomic weights is stressed in the chapter on "Calculations" by expressing atomic weights to the third decimal place. The role of ions in electrolysis is emphasized, p. 228, but the equally important part the electron plays fails to receive proper recognition. More exercises are needed to show the student how to use the tables and to appreciate their value. There are no lists of references at the end of chapters to stimulate and guide the ambitious student in further study. This help to both student and teacher will probably be supplied in a practical "Teacher's Manual," which the author has in preparation.

HERMAN SCHLUNDT

Properties of Inorganic Substances. A Second Revision and Enlargement of Tables of Properties of Over Fifteen Hundred Common Inorganic Substances. By WILHELM SÖGERBLÖM, A.B., Instructor in Chemistry at the Phillips Exeter Academy. The Chemical Catalog Company, Inc., 19 East 24th Street, New York, 1927. 226 pp. 23.5 × 16 cm. Price \$6.00.

The purpose of this book, as indicated by the author in the preface to the first edition, is to provide a list of properties of inorganic substances to corroborate tests made in qualitative analysis. The common metallic elements and compounds are grouped in the Fresenius order. Properties are tabulated in parallel columns, facilitating the comparison of thirty-six similar compounds of each of these elements. Thirty-four acids and about sixty less common elements are described in the closing fifty pages of the book.

The present edition is considerably larger than the first edition, and has, apparently, been revised in accordance with data made available during the past two years; about fifty per cent. new material has been

included. Quantitative data on solubilities replace qualitative statements made in the first edition, and a number of new compounds have been added to the tables of elements listed. In the opinion of the reviewer it is unfortunate that the price of the book is somewhat greater than the individual student may care to pay for a supplementary textbook.

There is little doubt that the amount of information a student of one or two year's experience in inorganic chemistry is called upon to acquire very greatly surpasses the amount expected from those who studied chemistry when the general sub-division of the subject, at present in vogue, was instituted. It is a natural result of a study of the needs and abilities of students that teachers are turning more to special aids to memory, such as this book, as a supplement to regular textbooks, and it is the opinion of the reviewer that most of those interested in the successful teaching of chemistry welcome these aids as a means of increasing the usefulness of the student's chemical training and improving his method of study.

While it is possible to list some typographical errors and items of doubtful value in this book, it appears that the general reader will not be helped in evaluating the work by such tabulation. In general, it may be said that the book is relatively free from errors, considering the nature and the wide variety of sources from which the information is necessarily drawn. The reviewer is inclined to approve the publication of such books, and feels that other teachers might well examine the descriptive material given in their courses with a view to rendering it more readily available for students.

C. R. HOOVER

Gmelins Handbuch der anorganischen Chemie. (Gmelin's Handbook of Inorganic Chemistry.) Edited by R. J. MEYER. Eighth edition, revised System—No 2 **Hydrogen.** Published by the Deutsche Chemische Gesellschaft, Verlag Chemie, G. m. b. H., Corneliusstrasse 3, Berlin W 10, Germany; 1927. xxi + 273 pp 3 figs. 18 × 26 cm. Price, to subscribers, 27 M.; singly, 34 M.

This volume follows closely the lines of the earlier instalments. There is first a single paragraph on the history of hydrogen, quite inadequate in itself and equally so in its references to the literature of the subject. There follow excellent sections on the occurrence, formation, preparation and manufacture of hydrogen, totaling 54 pages, and one on its physical properties, occupying 139 pages. Finally, there are sections of about 20 pages each, on the chemical properties of hydrogen, on the two forms of active hydrogen and on the hydrides. Aside from this connected account of the hydrides, the compounds of hydrogen with other elements are not discussed except incidentally, since hydrogen is preceded in the numerical system adopted for this handbook only by the inert gases.

The literature has been covered up to the end of 1926. The collaborators with the Editor in the preparation of this volume were Erich Pietsch, Reinhold Johow, Friedrich Struwe, Heinrich Böttger and Gertrud Wilcke.

ARTHUR B. LAMB

The Problem of Physico-Chemical Periodicity. By E. S. HEDGES AND J. E. MYERS. With a Foreword by Professor F. G. Donnan. Longmans, Green and Company, 55 Fifth Avenue, New York City, 1926. 95 pp. 15 figs. 22.5 × 14.5 cm. Price \$2.75.

The scope of this monograph is indicated by the titles of the chapters: I, Introduction. II, Static Periodicity ("where the periodic property is expressed in terms of some other quantity than time or distance"). III, Periodic Structures (for example, Liesegang rings). IV, Periodic Chemical Reactions. V, The Periodic Catalytic Decomposition of Hydrogen Peroxide. VI, Miscellaneous Periodic Reactions. VII, Periodic Electrochemical Phenomena. VIII, Periodicity and the Metastable State.

There is a Subject Index and a Bibliography arranged as an Author Index. The opinion of the authors that the bibliography is very nearly complete seems well founded.

"The examples of periodic chemical reactions which have been discussed are characterized in the main by heterogeneity of conditions." In the cases considered in Chapters IV and V "periodicity is only realized in the presence of a third constituent," and "the source of the periodicity is in this activating material." It is believed that this material is in a metastable, amorphous form. A close relation to catalysis is evident.

To quote Professor Donnan, "The present work may be warmly commended to the attention of biologists and geologists as well as chemists and physicists."

WILLIAM C. BRAY

Physico-Chemical Geology. By R. H. RASTALL, Sc.D., F.G.S. Longmans, Green and Company, 55 Fifth Avenue, New York City, 1927. vii + 248 pp. 62 figs. 22 × 14.5 cm. Price \$6.00.

This little book is the best of its kind that has come to the attention of the reviewer. It reminds one of the "Principles of Chemical Geology," by J. V. Eidsen. It is not a mere compendium of physico-chemical investigations, like the German texts, but discusses in a practical way selected topics in geology that are helpfully presented in terms of physical chemistry. Several chapters are first introduced on elementary physical chemistry, dealing with equilibrium, change of state, solutions, etc. The petrology that follows is then elucidated in those terms. This part of the subject matter may be indicated by some of the chapter headings: igneous rocks, mineral formation in igneous rocks, metamorphism, rock-weathering,

salt deposits, ore deposits, refractories and colloids in geology. This material has been critically selected and is consequently free from old, discarded or conventional explanations.

Comparatively few references to recent papers and texts are given. For much that is necessarily omitted in a book of this size the reader is referred to United States Geological Survey Bulletin 770, Clarke's Data of Geochemistry. Reference is also made to Boeke's *Grundlagen der phys.-chem. Petrographie*, 1915 edition, but not to the 1923 edition or to Eitel's *physikalisch-chemische Mineralogie und Petrologie*, 1925.

The author adheres to a few chemical terms used more by geologists than by chemists. He also shows a strong preference for British authorities in his references. The geologist should be benefited by the physical chemistry and the physical chemist will find considerable mineralogy, or, more broadly speaking, petrology, in this book. On the whole it is a happy dovetailing of the two fields. The chapter on metamorphism is especially good.

ROGER C. WELLS

Titanium. With Special Reference to the Analysis of Titaniferous Substances. By WILLIAM M. THORNTON, JR., Associate in Chemistry in the Johns Hopkins University. American Chemical Society Monograph Series. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York City, 1927. 262 pp 26 figs. 15.5 × 23.5 cm. Price \$5 00.

This book is one of the series of monographs prepared under the auspices of the American Chemical Society. It aims to present in compact form all the more important information which has heretofore been presented in dictionaries and in current literature on the subject of titanium.

An introductory section gives in broad outline the circumstances under which the metal was discovered, its occurrence in nature, a general account of the isolation of the metal and the preparation of its important compounds and their industrial applications.

A second section deals with the detection and estimation of titanium in its various associations. The analytical procedure is given in detail for rutile, ilmenite, ferro-titanium, titanium pigment and titanium zinc paint. In other cases the partial procedure is given for the isolation and estimation of titanium alone when associated with other metals. In this analytical section the author has performed a valuable service in collecting and in some cases critically reviewing the large mass of analytical information to be found only in current literature.

The last section gives the methods used by the author in preparing the various reagents with the necessary degree of purity, which are serviceable in the analysis of titaniferous materials.

The book is of special value to the analytical chemist. To the layman the introductory part may give the false impression that titanium plays

a more extensive role in chemical technology than it actually does. As the author states titanium is widely distributed throughout the earth's crust and occurs often in large aggregations from which titanium as oxide is easily extracted. Yet in spite of this it performs but a small function in industry. Its outstanding use is in the preparation of titanium pigments. The alloys of the metal, particularly with iron, have been used as "scavengers" in the past, but this outlet for the material, never very extensive, does not appear to be on the increase. Outside of these two functions the metal is but little used.

It would seem to the reviewer that the research chemist of the future has an important duty to perform in bringing the element titanium into the service of man. To this end Dr. Thornton has taken the first step in bringing all available information into the compass of one volume.

M. A. HUNTER

Colloid Chemistry, Theoretical and Applied, by Selected International Contributors. Collected and edited by JEROME ALEXANDER. Volume I. Theory and Methods. The Chemical Catalog Company, Inc., 19 East 24th Street, New York City, 1926. 974 pp. 324 figs. 16 X 24 cm. Price \$14.50.

This is the first volume of a three volume compendium on colloid chemistry. The sub-title of the first volume is Theory and Method; that of the second, Biology and Medicine; that of the third, Technology.

There are in this volume sixty contributions covering the most diverse branches of chemistry and physics, and for that matter of the other physical sciences. One will find not only papers dealing with the behavior of colloids in biology, geology and meteorology but there are papers even on the colloidal aspects of astronomy!

The list of contributors is remarkably cosmopolitan in character, almost every civilized country in the world being represented. It is also a very distinguished one; it includes five Nobel Prize winners.

The articles in general are not cursory and impromptu notes; they are for the most part well considered and thorough reviews of the particular field of colloid chemistry in which the authors are authorities, frequently accompanied by recent and previously unpublished accounts of new researches.

It is beyond the limits of this book review to list the titles of the sixty contributions. I shall, however, in order to indicate the scope of the collection, arrange the papers in classes and give the names of the authors as follows:

There are seven papers dealing with the general theories of colloids, by Jerome Alexander, P. P. von Weimarn, G. Friedel, E. Buchner, J. W. McBain, E. F. Burton, R. A. Millikan; four on surface energy, surface films, etc., by W. D. Harkins, W. H. Bragg, P. L. du Noüy, R. E. Wilson;

thirteen on processes of aggregation, on optical phenomena, meteorology and the cosmos, by W. E. S. Turner, W. B. Hardy, H. R. Kruyt, Albert Einstein, W. H. Martin, René Audubert, Hsien Wu and Daisy Yen Wu, W. E. Gibbs, Carl Barus, W. J. Humphreys, H. T. Barnes, H. N. Russell, W. D. MacMillan; six on thermal, electric and osmotic effects and on the critical state, by F. L. Browne and J. H. Mathews, Leonor Michaelis, J. Errera, J. Duclaux, Irving Langmuir, W. Kopaczewski; thirteen on various aspects of adsorption, by H. Freundlich, H. B. Weiser, Jerome Alexander, H. Wislicenus, H. J. M. Creighton, G. A. Hulett, J. Traube, T. Hagiwara, S. Utzino, A. Lottermoser, A. de G. Rocasolano, Richard Lorenz, L. L. Bircumshaw; three on viscosity, by E. C. Bingham, W. H. Herschel, Emil Hatschek; six on gels and diffusion, by S. C. Bradford, Dorothy J. Lloyd, R. E. Liesegang, H. N. Holmes, H. A. Endres; and finally eight on apparatus useful in colloid chemistry, by Max Poser, R. Zsigmondy, H. Bechhold, T. Svedberg, E. E. Ayres, Jr., Sven Odén, Henry Bassett.

This collection is a splendid achievement and a real tribute to the energy, enthusiasm and breadth of view of its Editor. Indeed, to have secured so distinguished a body of contributors and to have had them function individually and collectively with such success establishes him as an impresario of the first rank. Finally, his phrase in the Preface that "It is we who are simple, not Nature" deserves perpetuation.

ARTHUR B. LAMB

Enzymes: Properties, Distribution, Methods and Applications. BY SELMAN A. WAKSMAN, Associate Professor of Soil Microbiology, Rutgers University; Microbiologist, New Jersey Agricultural Experiment Station, and WILBURT C. DAVISON, Associate Professor of Pediatrics, Johns Hopkins University; Associate Pediatrician, Johns Hopkins Hospital (more recently, Dean of the School of Medicine, Duke University). The Williams and Wilkins Company, Baltimore, 1926. xii + 364 pages. 11 Figs. 23.5 X 15.5 cm. Price \$5.50.

The purpose of this book is stated by its authors in their preface as follows: "It has been our endeavor to collect in as concise form as possible the available information in regard to enzymes and to indicate the original sources from which more detailed knowledge may be obtained. Anyone who attempts a study of enzymes cannot fail to be struck by the vast accumulation of literature on the subject, while at the same time he will be confused by the many apparently contradictory results that have been published. Over two thousand references have been consulted—most of them in the original—the others in abstracts which have appeared in various journals. To piece these irregular and loosely fitting fragments together into a mosaic upon which future studies may rest is the object of this book." In the judgment of the reviewer, the authors in thus stating their purpose have also offered a word which well characterizes their work;

it is a carefully wrought mosaic rather than a unified thesis or a flowing narrative.

The section entitled "properties of enzymes" occupies 56 pages; "distribution of enzymes," 62 pages; "methods for the preparation and study of enzymes," 131 pages; "practical applications of enzyme activity," 14 pages; bibliography, 78 pages; index, 14 pages.

In view of the professional interests of the authors, as mycologist and physician respectively, it is natural to find that the medical and microbiological aspects of the subject are more fully developed than the technological or the purely chemical. Chemical theories of enzyme action are much less ambitiously treated than by Falk, and many descriptive matters are developed less fully than by Oppenheimer and Kuhn; but Waksman and Davison, defining enzymology as a branch of biology and reviewing with special care and thoroughness some of the more biological aspects, have also presented to the science of chemistry the best effort which the reviewer has yet seen to condense into a single readable volume, a judicial and reasonably symmetrical account of those whole fields of science in which enzymes play a dominant role and to connect effectively their concise text with the original literature of this comprehensive subject. And the chemist, realizing his debt to these authors, does not feel inclined to dwell too heavily upon the occasional loose use of a chemical term, as when zymases are said to "hydrolyze" sugar (p. 244), nor to complain too bitterly at a choice of boundaries which includes less well defined oxidases while omitting glutathione. Dogmatic statements are encountered to a somewhat greater extent than might be anticipated in view of the preface; but the prevailing tone of the book is commendably unbiased throughout, and its breadth of view and careful correlation of readable text with comprehensive bibliography will make it useful both to students of divergent interests who wish general information on enzymes and to special students of the subject who will profit by this introduction to the extensive original literature of both animal and vegetable enzymes, including those of the microorganisms.

Perhaps as an inevitable concomitant of its comprehensiveness, the text sometimes presents a compilation of opinions rather than an attempt to analyze the actual experimental evidence upon a doubtful or disputed point. It is a pity that this should result in a failure to recognize the importance of the excellent work upon the chemical nature of malt amylase which was published by T. B. Osborne in *THIS JOURNAL* over thirty years ago.

COPPER-CONSTANTAN THERMOCOUPLES AND THE HYDROGEN THERMOMETER COMPARED FROM 15 TO 283° ABSOLUTE

By W. F. GIAUQUE, R. M. BUFFINGTON¹ AND W. A. SCHULZE

RECEIVED NOVEMBER 17, 1926

PUBLISHED OCTOBER 5, 1927

One of the most important tasks of a laboratory engaged in low-temperature calorimetric and other measurements is the maintenance of a secondary thermometric standard.

Since 1918, the secondary standard of this Laboratory has been the four-junction copper-constantan thermocouple calibrated between 60 and 300°K. to an accuracy of 0.1° by Eastman and Rodebush.²

This thermocouple has been compared frequently with the freezing point of mercury since the original calibration, and has always been in closer agreement than the stated limits of accuracy.

However, for a number of reasons, the preparation of a new secondary standard has seemed necessary, the chief of these being the extension of the obtainable temperatures by the use of liquid hydrogen.

The gap between 15 and 60°K. has in some cases been bridged by making use of the triple- and boiling-point temperatures of hydrogen, but at best this leads to large uncertainties. For this reason, considerable data have for some time been withheld from publication, pending the conclusion of the work presented in this article.

Most of the recent calorimetric work in this Laboratory has utilized resistance thermometers which can be made much more sensitive and suitable for temperature interpolation than are thermocouples. This is especially true at very low temperatures.

However, at least for the immediate future, copper-constantan thermocouples were again chosen as the reference standard. This was primarily

¹ National Research Fellow in Chemistry, University of California.

² Eastman and Rodebush, *THIS JOURNAL*, 40, 489 (1918).

because they are much more convenient, and also because the experience with the Eastman-Rodebush standard couple had been satisfactory.

The convenience of thermocouples depends largely on the fact that they may, after calibration, be soldered to a metal apparatus, thus insuring excellent thermal contact. Resistance thermometers which may be detached for calibration have sometimes been used, for example, by Keesom and Onnes.³

It is expected that most cryogenic work in this Laboratory will, at least for some time, make direct use of fixed-resistance thermometers which are continuously calibrated during measurements by means of an attached thermocouple. This permits a precision in the measuring of small temperature intervals beyond that possible with a thermo-element alone, and at the same time furnishes a valuable check on the temperature measurements.

The effective portions of a thermocouple are those located in temperature gradients, and it is important that no inhomogeneities of a physical or a chemical nature occur at such places. When possible, tests for the effect of inhomogeneities should be carried out at temperatures approximating those at which the thermocouple is to be used. We believe that the use of liquid air as described is an unusually severe test.

The Thermocouple Wire

The Laboratory supply of constantan, consisting of 58 spools of various sizes and amounts, including 20 spools of No. 30 B. and S. gage, was tested. The e.m.f. against copper between 83 and 273°K. was measured in each case, and in most cases a loop was run through liquid air and galvanometer deflections were noted as a measure of imperfections. Sharp turns were prevented by means of a submerged glass U with a radius of about 6 cm. The warm ends of the loop were attached to copper and kept in an ice-bath. About 1.5 meters of each sample was pulled through, and the procedure was then reversed.

Table I shows typical results on the best constantan wire of various sizes. The deflections in the case of the poorer wire went as high as 10 microvolts, even in the larger sizes. It is evident from the data that very small wire should not be used. The severe gradient imposed by the test would be somewhat greater in the case of small wires, but the same situation might arise in the normal use of thermocouples.

TABLE I
TESTS ON CONSTANTAN WIRE

Size, B. and S. gage	25	30	35	40
E.m.f. vs. Cu at 83°K., microvolts	5468	5810	5791	5609
Av. e.m.f., microvolts	0.24	0.35	0.87	1.84
Maximum	.7	.8	2.0	3.1

³ Keesom and Onnes, *Comm. Phys. Lab. Leiden*, 143, 1914.

Table II shows the e.m.f.'s of some copper-copper thermocouples with junctions at liquid air and ice temperatures in each case. It is evidently necessary to use the same copper for all couples when close agreement is desirable for intercomparisons.

TABLE II
TESTS ON COPPER WIRE

E.m.f. vs. No. 36(a) junctions								
83 and 273°K., microvolts	+2.7	-0.5	-5.2	(0.0)	-0.2	-0.1	-27.1	+13.8

The Thermocouples

Since it was desired to solder the couples to apparatus, the use of multi-junction couples was eliminated. At the suggestion of Dr. D. H. Andrews, parallel constantan wires were used to average out, partially, small imperfections. This method has recently been used by Hovorka and Rodebush.⁴

Six thermocouples, designated as J, W, 15, 16, 17 and 18, respectively, were made. Each consisted of five No. 30 double-silk-covered constantan wires, and one No. 36 double-silk-covered copper leading to the variable junction. J and W each had five No. 36 copper leads to the individual constantan wires at the ice ends, while 15, 16, 17 and 18 had only one No. 36 copper lead from the ice end in each case. The five No. 30 constantan wires had about the same thermal conductivity as one No. 36 copper wire.

In addition to the above, one couple was made from another spool of No. 30 constantan, which gave 5494 microvolts when opposed to copper at 83 and 0°K. The loop test on this wire gave an average deflection of 0.34 and maximum deflection of 0.9 microvolt. Four parallel constantan wires with separate No. 36 ice ends were used. All of the couples, each of which was 268 cm. long, were wrapped with silk thread.

The Thermocouple Comparison Apparatus

All of the variable junctions were well soldered to a solid cylinder consisting of about 1 kg. of lead. This was suspended within a hollow lead and copper cylinder of about 1.2 kg., which was itself suspended within a brass container suitable for high vacuum.

Each couple was wound twice about the outer cylinder and three times around the inner one, 72 cm. being used in this way as a protection against heat leak into the junctions. The wires wound on the cylinders were heavily paraffined, and the whole was wound with adhesive tape.

Other details of construction and temperature control were quite similar to those of the final gas-thermometer apparatus, and will be described in that connection.

⁴ Hovorka and Rodebush, *THIS JOURNAL*, 47, 1614 (1925).

Table III shows some typical results of the constantan comparison. Col. 1 gives the approximate e.m.f. against copper. Cols. 2-6, inclusive, give the differences between the various parallel groups of constantan wires. Cols. 7-10 show the comparison of the individual constantan wires contained in the parallel group of J. All differences were determined with a galvanometer, using the double-deflection method. The reversing switch was located at the apparatus, thus practically eliminating any error from electrical leaks.

Comparison of the results on single wires and on parallel groups shows that the latter are considerably more reliable, as was to be expected. The algebraic signs are all consistent; thus, when $15\text{-Cu} = 5220.00$ and $J-15 = -0.45$, then $J\text{-Cu} = 5219.55$. Comparisons were made at intervals of about 10° .

TABLE III
TYPICAL RESULTS OF CONSTANTAN COMPARISONS

(Values are given in microvolts)									
15-Cu	J-15	W-15	16-15	17-15	18-15	5-6	5-7	5-8	5-9
6587	-0.63	-0.74	+0.11	+0.48	+0.30	-0.36	-0.42	-0.39	-0.46
6014	-.53	-.63	+.17	+.52	+.32	-.51	-.44	-.44	-.54

Thermocouple 17 was selected for comparison with the hydrogen gas thermometer.

The Hydrogen Thermometer

The hydrogen-thermometer comparison apparatus used differs considerably from instruments used for this purpose by others. It was modeled after a calorimeter for the investigation of liquefied and solidified gases used by Giauque and Wiebe for a series of measurements soon to be published.

The apparatus is shown in Fig. 1.

D is a vacuum-tight monel container with connecting tube shown at A. The cover of D was equipped with a cup (not shown) which could be filled with water as a protection for the wires while the cover was being soldered on. B is a 6kg. block of lead. F is a hollow cylinder of lead and copper weighing about 7.5 kg. and supported from the cover of D by stout cords. G is a vacuum-tight 1.5kg. copper and lead container for the thermometer bulb. The spaces between D and F and between F and G could be evacuated. C is a German silver tube leading from G through F and then out at the top of Tube A. The 0.8mm. capillary leading from the 194.3cc. Pyrex bulb, shown at H, was taken out through Tube C. Hydrogen gas could be admitted through Tube C to the space around the capillary and bulb. A rough manometer was used in keeping this pressure approximately equal to that within the bulb, thus eliminating the necessity of pressure correction on the bulb volume. At Position E the tube C was securely soldered to Cylinder F, and the space between the capillary and tube was filled with Rose's metal for a length of 2 cm., with the exception of two very fine thin-walled glass tubes for the passage of hydrogen. Also, the capillary was wrapped at intervals of 2 cm. with narrow strips of adhesive tape until the space between the capillary and Tube C was nearly tight at these points.

The purpose of the adhesive tape and of the Rose's metal was to minimize longitudinal and insure radial conduction. F and G were equipped with electric heaters for temperature control. Control thermocouples were attached to D, F and Tube C at points 20, 40 and 60 cm. above Position E. The temperature at 80 cm. above Position E was taken with a mercury thermometer in a cup attached to a copper case which also enclosed the capillary leading to the manometer. These temperatures were necessary in making the correction for the amount of gas in the capillary.

The top of Tube C was attached to the capillary by means of rubber tubing and de Khotinsky cement to avoid strain by unequal expansion. All wires were taken out through de Khotinsky cement.

Fig. 1.

Production and Control of Low Temperatures

All temperatures below room temperature were produced by either liquid air or liquid hydrogen at normal or reduced pressures. For example, at temperatures above 100°K., liquid air was used in small quantities, so that no great temperature difference existed between Container D and Cylinder F, Fig. 1. The apparatus was first cooled to the lowest desired temperature, Container D being filled with several centimeters' pressure of hydrogen to supply the necessary conduction. Container D was then evacuated to a pressure of about 10^{-5} mm. of mercury or better. Cylinders F and G were then easily adjusted to equal tempera-

ture by means of their electric heaters. The high vacuum reduced the heat leak to such an extent that the temperature of Cylinder G would not change by 0.01° during the course of a measurement.

Placing of Thermocouple

Thermocouple No. 17 was soldered to the lower portion of container G. It was also otherwise placed as nearly as possible in the same manner as that used in the comparison apparatus. Particular attention was paid to having the temperature gradient occur in the same portion of the wire.

The Manometer

The manometer and auxiliaries are shown in Fig. 2. J and L indicate the arms of the manometer, the inside diameter of each being about

Fig. 2.

1.2 cm. L also indicates a very close-fitting monel plug, carrying the thermometer capillary and cemented in with melted shellac and de Khotsinsky cement. A 0.07cm. tip, which was off center in the line of vision, projected from the lower side of the monel plug as a reference point in adjusting the mercury level in that arm. See the description of the manometer used by Cath and Onnes.⁵ A standard meter is shown at K. M shows the mercury reservoir with central stopcock at N. The capillary shown near O was a partial guard against rapid flow of mercury in case Stopcock O was opened while the manometer was out of balance. P shows a rubber tubing with clamp actuated by a screw worked by a series of reduction pulleys through Shaft Q. This permitted a fine adjustment of the mercury level. Tube I was attached to an evacuating system with mercury-diffusion pump and McLeod gage. The hydrogen was admitted

through Tube I before filling with mercury.

All of the apparatus shown in Fig. 2 was enclosed in a tight wooden case with a plate-glass window. The temperature of the case was controlled by a stream of air from the Laboratory compressed-air system. This gave a temperature which varied very slowly with time. The lighting of the menisci and meter was by means of focusing flashlights and a spotlight, all located far enough away to avoid large heating effects, and was used intermittently. The temperature of the mercury was obtained by means of four mercury thermometers.

⁵ Cath and Onnes, *Comm. Phys. Lab. Leiden*, No. 156a, 1922.

Pressure Measurements

The pressure measurements were made by using a Société Générale cathetometer for the comparison of the mercury menisci with the nearest millimeter ruling on the standard meter. The accuracy was 0.02 mm. The manometer case was tapped before each measurement to prevent sticking of the menisci. Since there was a high vacuum over the mercury in Tube J, direct pressure readings were secured. The correction for meniscus depression was that given in the International Critical Tables.⁶ Since both arms of the manometer were of the same diameter, this correction was nearly balanced out.

Electrical Measurements

Two White double potentiometers were used simultaneously for the electrical measurements, one for the control thermocouples, and one of 10,000 microvolts' range with a galvanometer of low critical ramping resistance for the standard couple. The latter potentiometer was calibrated.

All wiring between the apparatus and potentiometer was supported from the lower side of highly insulating strips of Bakelite, and the whole system electrically shielded.

Temperature Variation of Bulb Volume

The correction for the diminution of bulb volume at low temperatures was made possible by the expansion measurements of Buffington and Latimer⁷ on Pyrex. Their measurements extend only to liquid-air temperatures, thus necessitating considerable extrapolation. Fortunately, however, the nature of the correction is such that it becomes less important at very low temperatures.

The Obnoxious Volume

The obnoxious volume consists of the connecting capillary and the volume between the mercury meniscus and the monel plug. The latter volume was calculable from meniscus data in the International Critical Tables.⁸ Data for this calculation were secured with each measurement.

In making the correction for the amount of gas in that section of the capillary within the temperature gradient, a graphical method was used.

Preparation and Purity of Hydrogen

The preparation of the electrolytic hydrogen was the same as that described by Latimer, Buffington and Hoenshel,⁹ except that the rate of

⁶ International Critical Tables, McGraw-Hill Book Co., New York, 1926, vol. I, p. 70.

flow over the nickel catalyst used for removing oxygen was 0.1 cu. meter per hour, and an extra tube of nickel catalyst was used as an added precaution. Although hydrogen prepared in the above manner contains less than 0.01% of oxygen, it was still further purified by standing over charcoal at liquid air temperature. The charcoal had previously been heated and pumped with a mercury diffusion pump.

Filling the Thermometer

The thermometer bulb was evacuated with a mercury diffusion pump and swept out with pure hydrogen several times before the final filling. The evacuation was slow because of the small diameter of the capillary. More than a week was required for the above procedure.

Reconstruction of Apparatus

After the completion of runs referred to as 1 and 2, one of the supports of the heavy cylinder gave way, and the capillary leading to the manometer snapped off. Also, after removal, thermocouple No. 17 proved to have developed a short circuit. The apparatus was repaired and Thermocouple J was used instead of immediately repairing No. 17. The silk insulation of 17 was easily repaired later. The bulb was refilled with hydrogen, and runs designated as 3, 4 and 5 were made. The reconstructed apparatus and new thermocouple proved to be a valuable check on the previous measurements.

The Ice Point

It was realized in the designing of the apparatus that the thermometer bulb could not be brought with sufficient accuracy to the ice point by surrounding the whole apparatus with ice; in fact, this experiment was not tried. However, it has been shown that the maximum difference in e.m.f. between any of the couples when the variable junctions were at the ice point was 0.07 microvolts, corresponding to 0.002°. This

TABLE V
ICE-POINT PRESSURES

enabled the ice point to be obtained by adjusting the temperature of the heavy cylinders until the thermocouple reading was zero, or nearly so. Table V shows the ice-point data.

The ice-point pressure gradually increased during Runs 1 and 2. The apparatus was known to be tight at the start by test with a McLeod gage before filling, but considerable difficulty was encountered in displacing the hydrogen by mercury in Tube P, Fig. 2, and small bubbles were observed on several occasions in the adjoining tube. The gas eventually rose into Tube J and was pumped off, but some apparently was carried into Tube L, Fig. 2, on the few occasions when the mercury moved rapidly through the capillary U. There is also some possibility that the plug in the bottom of Tube P leaked slightly, which might admit some air. If the gas were hydrogen it would make no difference as to the results, while even if it were air the effect would not exceed 0.01° in the most unfavorable case.

Before Runs 3, 4 and 5, Tube P was renewed and filled with mercury before hydrogen was admitted. The pressure then showed a slight decrease with time. The result marked *a* was obtained after rapidly heating the bulb from the neighborhood of liquid-air temperatures, and may indicate some temperature lag in bulb volume as well as the effect of other unfavorable conditions.

Most of the measurements were made by four observers simultaneously recording the various data.

Treatment of Results

The data were treated as follows. An approximate temperature scale (accurate to a few tenths of a degree) was calculated. The various corrections could then be applied, giving a table of e.m.f. and temperatures on the hydrogen scale. The data of Cath and Onnes⁵ were used for correcting the temperatures from the hydrogen to the thermodynamic scale.

A plot of $\Delta\epsilon/\Delta T$ against T was constructed. Approximate $d\epsilon/dT$ and ϵ values were chosen. First and second differences of the $d\epsilon/dT$ values were tabulated. The approximate table was used to calculate the individual points. Guided by the above comparison, the $d\epsilon/dT$ differences were smoothed, and the final Table VI was constructed for Thermocouple 17. Fig. 3 shows the comparison of the temperatures given by the gas thermometer with those calculated from the thermocouple readings by means of Table VI. No absolute significance is to be attached to the data in Table VI, but it should prove useful in the construction of deviation plots for interpolating data of other thermocouples when only a few points are available. This is the method suggested by Adams,¹⁰ but his data extend only to liquid-air temperatures. An

¹⁰ Ref. 6, p. 57.

equation method could be used, but aside from the considerable difficulty in obtaining an equation to fit the observed data, we believe the deviation plot to be the more advantageous method.

Since the completion of the work considered in this paper, Giaque, Johnston and Kelley have made a comparison of the scale here obtained with the hydrogen and oxygen vapor-pressure thermometers. This work, which is described in a following paper,¹¹ shows that the measurements below 25°K. are in error, presumably due to adsorption of hydrogen within the thermometer. We have accordingly extended Table VI only to 25°K. The extension of Table VI to 13°K., as well as a discussion of the adsorption effect, will be found in another paper.¹¹

The results between 87 and 128°K. in Run 2 show the effect of neglect with regard to the ice junction. The ice had been in use for nearly 20

¹¹ Giaque, Johnston and Kelley, *THIS JOURNAL*, **49**, 2367 (1927).

hours when this effect took place. The result at 264°K . in Run 5, which deviates by 0.07° , was taken after rapid warming from 138°K . and may indicate lag in the Pyrex bulb. The ice point immediately following this measurement was also off in the same direction. The greatest lack of agreement seems to be in the range where the obnoxious volume correction is most important, that is, at about 140°K . The effect of having the temperature gradient larger or smaller than was normal for the apparatus as used seems to be quite definite. It is difficult to segregate the effect on the gas thermometer from that on the thermocouple, but we suspect the latter. To our knowledge there is no theoretical or experimental reason to suppose that the irreversible heat flow which is necessarily

× Run 1. • Run 2. Δ Run 3. □ Run 4. ○ Run 5. A, new ice on junction; B, temperature gradient large as possible, C, temperature gradient small as possible

Fig. 3.—Deviation graph.

present in thermocouples may not be contributing appreciably to the e.m.f., and if so the amount due to this factor may depend on the character of the gradient. The effect referred to is of course not to be confused with those due to inhomogeneity. However, regardless of the nature of the small disturbances always observed in the use of thermocouples, it is obviously desirable to calibrate thermocouples under conditions nearly the same as those which exist when they are used.

The agreement of results with Thermocouples 17 and J was satisfactory. All of the results with J are expressed in terms of No. 17.

In connection with other experimental work, as yet unpublished, initial comparison with the temperature scales of others is available. Giauque and Wiebe have measured the vapor pressure of hydrogen chloride, using Thermocouple 18 as a reference standard. The results agree with those

of Henning and Stock¹² to one or two hundredths of a degree. This agreement is particularly significant since the work of Henning and Stock in the *Physikalisch-Technischen Reichsanstalt* was for the purpose of establishing thermometric standards. Their hydrogen chloride data extend from 156 to 186°K.

Before the hydrogen thermometer measurements were made, the e.m.f. of Thermocouple 17 in melting mercury had been measured. From Table VI this e.m.f. corresponds to a temperature of 234.18°K. The value given in the International Critical Tables is 234.23°K. The agreement is satisfactory, especially considering that the temperature gradient in this case was not in the same portion of the wire in which it occurred during the calibration. Other investigations in progress in this Laboratory will provide still other comparisons.

The results above 25°K. are believed to be accurate to 0.05°, which is considered quite satisfactory for present requirements.

The research described in this paper has been regarded as of a laboratory rather than an individual nature, and many besides the co-authors have contributed. We wish to express our thanks to W. M. Latimer, D. H. Andrews, H. D. Hoenshel, S. S. Shaffer, and particularly to R. Wiebe and H. L. Johnston, who assisted in making Runs 1 and 2.

Summary

The testing of constantan and copper wires for thermocouple use at low temperatures has been described.

The comparison of copper-constantan thermocouples with each other and with the hydrogen gas thermometer from 15 to 283°K. has been carried out, and considerable information is given as to what may be expected of carefully prepared thermocouples over the above range.

A gas thermometer has been described with which it is easily possible to obtain and maintain to 0.01°, for sufficient time, any temperature from that of liquid hydrogen to room temperature.

A table showing the properties of a typical copper-constantan thermocouple from 25 to 283°K. is included.

THE REACTION OF SODIUM CHLORIDE IF ADDED TO A SOLUTION OF LITMUS AND MERCURIC CHLORIDE¹

By WILLIAM OVID MOOR

RECEIVED JANUARY 13, 1927

PUBLISHED OCTOBER 5, 1927

It has been known for many decades that an aqueous solution containing either equivalent amounts of mercuric chloride and sodium chloride or sodium chloride in excess, does not change the color of blue or violet litmus, whereas a solution of corrosive sublimate alone has an acid reaction. I was indeed able to convince myself that red, violet or blue litmus did not react in any way with a solution containing mercuric chloride and sodium chloride, if the latter was present in an equivalent proportion or in excess to mercuric chloride.

This phenomenon has been explained on the ground that chloride of sodium and bichloride of mercury form a double salt, $\text{HgCl}_2 \cdot \text{NaCl} \cdot \text{H}_2\text{O}$, the reaction of which is neutral. For this reason further study and experimentation will be required to find an adequate explanation for the reaction to be described in the following.

It has been of great convenience to me in the course of my researches that I found a method which enabled me to obtain, whenever needed, a standard violet solution of litmus. By dissolving in a diluted solution of blue litmus some sulfate of zinc, we obtain a liquid which has exactly the same violet color as the best neutral tincture of litmus (for example, Kahlbaum's of the same dilution).² If the blue solution of litmus is not too concentrated, and if the sulfate of zinc has not been used too much in excess, no precipitate will form. By recurring to this method it will be made possible for every laboratory to use neutral solutions of litmus, possessing exactly the same shade of color.

In order to carry out successfully the reaction which forms the subject-matter of this communication, the following requisites should be kept ready on hand:

1. Two test-tubes of small caliber (about 1 cm. in diameter), each containing about 5 cc. of water.
2. A saturated solution (15–20°) of chloride of sodium.
3. A small measuring cylinder containing about 1.25 cc. of this saturated sodium chloride solution.
4. A filtered solution of 2 g. of blue litmus in 30 cc. of water. It is advisable to dissolve the litmus in warm water (50°).
5. Crystallized sulfate of zinc.
6. A solution of 1 drop of concd. hydrochloric acid in 40 cc. of water.

¹ From a paper read before the Chemical Society of Leningrad, on March 4 and April 1, 1926.

² I do not know whether this fact is known to chemists or not.

7. A 2% aqueous solution of bichloride of mercury.
8. Neutral violet litmus paper of the best sort.

Care must be taken that the chloride of sodium which is used here should be of absolutely neutral reaction, so that its saturated solution does not change the color of neutral litmus paper one way or the other. It sometimes happens that even "pure" sodium chloride shows a slightly alkaline reaction if tested with violet litmus paper. In such cases a saturated solution of the salt must be mixed, drop by drop, with a solution of one drop of hydrochloric acid in 40 cc. of water until sensitive neutral litmus paper, when moistened with the liquid, does not assume a tint of blue.

The reaction itself is carried out in the following manner. Five cc. of water is mixed first with 1-2 drops of the blue litmus solution, and then with some crystallized sulfate of zinc. We thus obtain a standard violet solution of litmus. Now we add to another 5 cc. of the diluted blue litmus solution, drop by drop, the above-mentioned solution of one drop of hydrochloric acid in 40 cc. of water, until the two liquids possess exactly the same color. The second 5 cc. of the neutral violet litmus solution is now mixed with 4-5 drops of a 2% aqueous solution of bichloride of mercury, whereupon the mixture at once becomes reddish. On quickly adding to this reddish liquid about 1 cc. of a saturated sodium chloride solution, the mixture, against all expectation, does not assume its original violet color, *but turns blue*.³

For properly estimating the shades of color of these various liquids it is necessary to use test-tubes of a small caliber and to hold them above the level of the eyes, so that the sky shines through the liquid. It need hardly be mentioned that this reaction must be carried out by daylight, the use of artificial light being very misleading.

Supplementary Note on the Reaction of Sodium Chloride with a Solution of Litmus and Mercuric Chloride.—Using the same quantities of the two solutions, sodium chloride and mercuric chloride, as in the original experiment, it makes no difference whether the mercuric chloride is added to the sodium chloride, or the sodium chloride to the mercuric chloride, as long as the litmus is added *last*. In both cases the solutions exhibit a neutral reaction.

If the original experiment is modified by varying the time allowed for the interaction of litmus and mercuric chloride from nearly zero minutes to several hours, the solution, on adding sodium chloride in excess, turns just as blue as in the original reaction. Even when the liquid containing litmus and five drops of the 2% solution of mercuric chloride was boiled for a few seconds the characteristic blue reaction with sodium chloride did not fail to take place.

³ After a few seconds the liquid gradually turns violet.

Only the best kind of litmus should be used, a diluted solution of which has a genuine blue color. It must be mentioned that the degree of blue produced by the sodium chloride is a shade less intense than that produced by adding potassium hydroxide to a neutral violet solution of litmus.

An adequate explanation of the *modus operandi* of the reaction between sodium chloride and litmus + mercuric chloride must account for the following facts.

1. The reaction takes place only if *first* the mercuric chloride has come in contact with the litmus.

2. The blue color produced by the sodium chloride is not lasting; in a few minutes the liquid assumes a violet color.

3. The blue color of the reaction is a shade less deep than the one produced by potassium hydroxide; the solution possesses a tint of lilac, which is not noticed if potassium hydroxide is used instead of sodium chloride.

THE CRYSTAL STRUCTURES OF MERCURIC AND MERCUROUS IODIDES

BY MAURICE L. HUGGINS AND PAUL L. MAGILL

RECEIVED MAY 2, 1927

PUBLISHED OCTOBER 5, 1927

Introduction

Since the determinations of the crystal structures of the mercury iodides here described were completed (in the summer of 1925) other investigators, as shown below, have published x-ray analyses of these substances, their conclusions being substantially in accord with our own. It seems desirable, nevertheless, to publish in brief form our measurements and deductions as they afford an independent confirmation of the results obtained, as our methods of obtaining and utilizing the data differ from those employed by the others, and as our structure determinations are more nearly unique.

This research was carried on while the senior author was a National Research Fellow at the California Institute of Technology. Some of the apparatus used was bought with the aid of a grant to Dr. A. A. Noyes from the Carnegie Institution of Washington. We wish to express our thanks for this aid and also to thank Dr. R. G. Dickinson for the use of apparatus designed by him and for personal instruction in methods of crystal-structure analysis.

A. MERCURIC IODIDE

The red modification of mercuric iodide, HgI_2 , is said¹ to crystallize with ditetragonal bipyramidal (D_4^h) symmetry. The axial ratio¹ (c/a) has been determined as 2.008 and the density² as 6.283 g./cc. The crystals exhibit very perfect cleavage parallel to the (001) faces.

Determination of the Structure from Spectral Photographs Alone

Spectral photographs were obtained, using the Mo K radiation with (1) the c axis, (2) the crystallographers' a axis, and (3) the other possible a axis (making an angle of 45° with that chosen by the crystallographers), as the axis of rotation. All of the reflections observed (from 48 different forms) could be given integral indices on the basis of a unit having the dimensions $a_0 = 4.34 \text{ \AA.}$ and $c_0 = 12.34 \text{ \AA.}$, but not on the basis of any smaller unit. Larger units would leave many unaccounted for absences. These exact values were obtained by direct comparison of the (110) and (001) reflections with those from a cleavage face of calcite.

A unit of this size contains two Hg and four I atoms, the calculated density being 6.45 g./cc. The axial ratio is 2.84, which is just $\sqrt{2}$ times the crystallographers' value. The factor $\sqrt{2}$ arises from the fact that the

² International Critical Tables, Vol. 1.

a axes of the true (namely, the smallest) unit make 45° angles with the a axes chosen by the crystallographers.

The considerations leading to the determination of the arrangement of atoms within the unit are as follows.

1. In each of the spectral photographs the half above the horizontal zone was an exact mirror image of that below this zone.

2. The "special positions" of the correct space group must include either two single non-equivalent positions or a pair of equivalent positions, for the mercury atoms.³

3. The reflections obtained included some from planes of each of the following classes: $(h + k + l)$ odd. $h = 0$; k odd. $h = 0$; l odd. $h = 0$; $(k + l)$ odd. $(h + k)$ odd.⁴

4. All odd order reflections from the (001) planes were absent, although even orders through (008) were obtained. Similarly, odd orders of (010) were absent, although in proper position for reflection.

5. The (110) reflection was absent or extremely weak on photographs showing moderately strong (220) reflections. Moreover, (004) reflections were absent or very faint on photographs showing fairly strong (006) reflections.

6. Certain structures would place the Hg atoms in layers 6.17 Å. apart, with the I atoms either all crowded together in the same planes as the Hg atoms or distributed between alternate layers of Hg atoms, the distance between Hg layers separated by I atoms being the same as between Hg layers having nothing between them. Such structures obviously could not be correct.

Only one tetragonal structure satisfies the requirements imposed by the above considerations. In that, which may be derived from either of the space groups V_d^4 , D_4^0 , or D_{4h}^{15} , the Hg atoms are at the positions (0,0,0) and $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$, and the I atoms at $(0, \frac{1}{2}, u)$, $(\frac{1}{2}, 0, \bar{u})$, $(\frac{1}{2}, 0, \frac{1}{2} - u)$ and $(0, \frac{1}{2}, u + \frac{1}{2})$.

To determine the value of the parameter u it is necessary to use further intensity comparisons. Great care must be exercised in making use of such comparisons from rotation spectra, since the relative intensities of two spots on the photographic plate depend on a number of other factors besides the relative reflecting powers of the two sets of planes being compared. It would seem safe, however, to use comparisons between spots which are fairly close together on the plate and which differ considerably in intensity, provided the stronger reflection is that further

³ The "equivalent positions" of the various space groups have been tabulated by Wyckoff, "The Analytical Expression of the Results of the Theory of Space Groups," Carnegie Inst. Pub. No. 318 (1922).

⁴ Absences to be expected from the various structures have been tabulated by Astbury and Yardley, *Trans. Roy. Soc. (London)*, 224A, 221 (1924).

from the spot produced by the direct beam. A number of such comparisons are listed in Table II.

TABLE II

OTHER COMPARISONS (FROM OTHER SPECTRAL PHOTOGRAPHS)

012, 013, 026, 028, 015, 016 > 002. 006, 008, 013, 015, 016, 017, 018, 019, 026, 028 > 004. 020 > 011. 018, 019 > 014. 028 > 019.

On calculating and plotting the structure factors in the usual manner, it has been found that these comparisons are all satisfied only for the parameter range from $u = .131$ to $u = .150$, if the Hg and I atoms scatter in proportion to their atomic numbers, for a slightly smaller range if the ratio, Hg/I , of their scattering powers is somewhat less than that of their atomic numbers, and for a slightly larger range if the scattering power ratio is somewhat greater than the atomic number ratio. The relative intensities calculated for the planes listed in Table I, assuming $u = .140$ and that the reflecting powers are proportional to the atomic numbers and not correcting for different interplanar distances, are given in the last column of that table.

Corroboration of the Structure with the Aid of Laue Photographs

This structure determination was checked by means of Laue photographs, the analysis being made in the usual way.

TABLE III
USEFUL DATA AND COMPARISONS FROM LAUE PHOTOGRAPH HgI₂-11

Indices	Est. intens.	Interpl. dist., Å.	Wave length, Å.	Indices	Est. intens.	Interpl. dist., Å.	Wave length, Å.

325	1.6	1.08	.43	5,2,11	.1	.65	.46
1,2,10	1.3	1.04	.44				

Comparisons: 235 > 234. 0,1,12 > 235. 1,2,16 > 1,1,16. 1,2,10 > 234. 0,1,12 > 1,2,10. 2,5,11 > 258.

By means of intensity comparisons between planes reflecting the same wave length, it was found possible to limit the parameter to quite a small range, namely, between .136 and .142 if we assume reflecting powers

proportional to the atomic numbers, between .138 and .142 if we assume the ratio ($\overline{\text{Hg}}/\overline{\text{I}}$) of reflecting powers to be 10% greater than that of their atomic numbers, and between .136 and .140 if we take $\overline{\text{Hg}}/\overline{\text{I}}$ as 10% less than the atomic number ratio. The uneliminated region disappears entirely if the ratio of scattering powers is assumed to be 22% greater or 28% less than that of the atomic numbers. In view of these results we believe $u = .140 \pm .003$ to be a conservative estimate of the parameter.

Comparison with the Results of Other Investigators

Havighurst,⁵ using powder photographs and ionization spectrometer measurements from single crystal faces, has determined the dimensions of the unit cell as $a_0 = 4.356 \text{ \AA.}$ and $c_0 = 12.34 \text{ \AA.}$ Bijvoet, Claassen and Karssen,⁶ using powder photographs and rotation spectra, have obtained $a_0 = 4.38 \text{ \AA.}$ and $c_0 = 12.43 \text{ \AA.}$ and deduced the same type of arrangement as have we, with $u = .139 \pm .007$.

Description and Discussion of the Structure

The structure (Figs. 1 and 2) may be described as consisting of "layer molecules." The smallest interatomic distance (Hg-I) within each layer, taking u as .140, is 2.77 \AA. ; the shortest distance between atoms (I-I) in different layers is 4.10 \AA. Within each layer each Hg atom is surrounded tetrahedrally by four equidistant I atoms and each I by two

Fig. 1.—The unit cell of HgI_2 . Large dots represent Hg centers and large circles and circled dots I centers. Small circles show the probable approximate "positions" of pairs of valence electrons.

⁵ Havighurst, *Am. J. Sci.*, **10**, 556 (1925).

⁶ Bijvoet, Claassen and Karssen, *Proc. Acad. Sci. Amsterdam*, **29**, 529 (1926).

equidistant Hg atoms. These atoms we may assume to be held tightly together, while the forces between the layers are, relatively weak accounting for the fact that these crystals cleave so readily parallel to their (001) faces.

The most probable distribution of valence electrons⁷ would seem to be that shown in the figures, both Hg and I kernels being tetrahedrally surrounded by electron pairs.

Fig 2.-A small section of a layer in a crystal of HgI_2 .

Assuming such a distribution and defining an atomic radius as the distance from nucleus to the center of a valence pair, it is evident that the distance between Hg and I centers equals the sum of their radii.

One of the authors⁸ has calculated the Hg and I radii, in crystals such as HgS , CuI and AgI , to be about 1.50 Å. and 1.25 Å., respectively. The sum of these values (2.75 Å.) is closer to the observed Hg-I distance (2.77 Å.) than might have been expected, considering

the inaccuracies of the calculations and the differences between the crystals involved.

B. MERCUROUS IODIDE

Crystals of mercurous iodide, Hg_2I_2 , are also tetragonal, with an axial ratio of 1.673 and a density of 7.70 g./cc. Cleavage again is parallel to the (001) planes.

Determination of the Structure

The unit cell found to be in agreement with both the Laue and spectrum data contains four Hg and four I atoms, a_0 and c_0 being 4.92 Å. and 11.64 Å., respectively. The a_0 value was obtained by direct comparison of a (110) reflection spectrum with that from a calcite cleavage face; c_0 was calculated from a_0 , assuming the axial ratio given above to be correct (except for the factor $\sqrt{2}$). This c_0 value was checked approximately

⁷ Cf. Huggins, *Phys. Rev.*, 27, 286 (1926).

⁸ Huggins, *ibid.*, 28, 1086 (1926). New and better data not then available (especially Barth and Lunde, *Norsk geol. tids.*, 8, 281 (1925) and Zachariasen, *ibid.*, 8, 302 (1925)) result in values for some of the radii which differ somewhat from those published. The newer values are used here.

by means of transmission spectra from the (001) planes. The calculated density is 7.68 g./cc.

In determining the type of arrangement within the unit the following observations were found useful:

1. Both spectrum and Laue photographs were symmetrical about lines passing through the central spot.
2. No $(h + k + l)$ odd reflections appeared.
3. Reflections were observed from planes of the following classes: $h = 0$; k odd; l odd. $h = \pm k$; $(2h + l)/4$ not integral. h odd; k odd; $l/4$ integral.
4. $l = 3$ reflections were all absent or extremely weak.
5. $l = 2$ and $l = 6$ reflections were all absent or too faint to be observed.
6. The reflection from (130) was stronger than that from (121).

Applying these data to all tetragonal structures and considering $\overline{\text{Hg}}/\overline{\text{I}}$

Comparisons: $l = 0 > l = 1, 2, 3$. $1 > 2, 3$. $4 > 1, 2, 3, 6$. $5 > 1, 2, 3, 6$. $7 > 2, 3, 6$. $8 > 1, 2, 3, 6$.

for all values from 1.00 to 2.00, all but the following have been definitely ruled out:

1. C_{4v}^9 (aa,aa). Hg at $(0,0,0)(\frac{1}{2},\frac{1}{2},\frac{1}{2})(0,0,u)(\frac{1}{2},\frac{1}{2},u + \frac{1}{2})$. I at $(0,0,r)(\frac{1}{2},\frac{1}{2},v + \frac{1}{2})(0,0,w)(\frac{1}{2},\frac{1}{2},w + \frac{1}{2})$.

2. (e,e) of V_d^9 , V_d^{11} , D_4^9 or D_{4h}^{17} ; (f,f) of V_d^9 . Hg at $(0,0,u)(0,0,\bar{u})(\frac{1}{2},\frac{1}{2},u + \frac{1}{2})(\frac{1}{2},\frac{1}{2},\frac{1}{2} - u)$; I at $(0,0,v)(0,0,\bar{v})(\frac{1}{2},\frac{1}{2},v + \frac{1}{2})(\frac{1}{2},\frac{1}{2},\frac{1}{2} - v)$. The second is a special case of the first, obtained by putting $w = u - v$ and shifting the origin.

The C_{4v}^9 structure cannot conclusively be eliminated without very tedious calculations. These we have not made, as they seemed unnecessary in view of the satisfactory agreement obtained otherwise and the absence of any crystallographic or other evidence of polarity.

Calculating structure factors for arrangement (2) for various values of l , u , v and $\overline{\text{Hg}}/\bar{I}$, the best agreement with our data (Tables IV and V) was obtained for $u = .117$ and $v = .353$, with $\overline{\text{Hg}}/\bar{I} = 1.3$ times the ratio

From powder photographs and ionization spectrometer measurements on Hg_2Cl_2 . The parameter values were calculated on the assumptions that $v - u = .250$ and that the Hg-Hg distance = 2.40 Å. in each case.¹² Havighurst, *THIS JOURNAL*, 48, 2113 (1926). The parameter values were obtained from calculations of the density of scattering power for x-rays at points on the tetragonal axis. These are undoubtedly more accurate than the earlier values.

of the atomic numbers (see Table VI). Although the true values of the parameters may differ slightly from these, greater differences than 0.01 would seem to be very improbable.¹³

Fig. 3.—The unit cell of Hg_3I_2 .

Description and Discussion of the Structure

The arrangement of atomic centers within the unit cell is shown in Fig. 3. It is apparent that the structure can be considered as an aggregation of IHgHgI "molecules," so distributed as to surround each Hg atom by four I atoms in other molecules and *vice versa*. The shortest distances between atoms, calculated from our values of the unit distances and parameters, are as follows. Hg-Hg, 2.72 Å.; I-I, 3.42 Å.; Hg-I (on same tetragonal axis), 2.75 Å.; Hg-I (not on same tetragonal axis), 3.65 Å.

If there are two valence electrons per Hg atom and seven per I atom, there are just sufficient for a complete octet around each I kernel and a pair between each two adjacent Hg kernels. It would seem reasonable to assume that each I valence shell consists of four electron pairs tetrahedrally disposed, as in the case of HgI_2 , but the orientation of these tetrahedra cannot at present be determined.

¹³ For no combination of parameters and ratio of reflecting powers was complete agreement obtained. For this reason we thought it advisable to postpone publication until our comparisons could be checked by new data, and others obtained. Although up to the present time it has not seemed feasible to do this, further delay in publication would appear to be unnecessary, in view of the agreement between our results and those published by others. Havighurst's 1926 parameter values give no better agreement than ours, no matter what ratio of $\overline{\text{Hg}}/\overline{\text{I}}$ is assumed (see Table VI). The reason for the disagreement is probably that the assumption that the atoms can be treated as point-scatterers is probably not valid when considering reflections from very complicated planes.

Summary

The crystal structure of tetragonal HgI_2 has been determined, (a) using spectral photographic data alone, and (b) using data from Laue photographs, together with spectra from the (100), (110) and (001) planes. The unit (Fig. 1) has the dimensions $a_0 = 4.34 \text{ \AA.}$ and $c_0 = 12.34 \text{ \AA.}$ and contains Hg atoms at $(0,0,0)$ and $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ and I atoms at $(0, \frac{1}{2}, u)$, $(\frac{1}{2}, 0, \bar{u})$, $(\frac{1}{2}, 0, \frac{1}{2} - u)$ and $(0, \frac{1}{2}, u + \frac{1}{2})$, with $u = .140 \pm .003$. The valence electrons are probably in pairs at tetrahedron corners around both Hg and I atoms, each Hg being bonded to four I atoms and each I to two Hg atoms. The structure may be said to consist of "layer molecules." The interatomic distance (Hg-I) within each layer is 2.77 \AA. The shortest distance (I-I) between atoms in different layers is 4.10 \AA.

The unit of Hg_2I_2 is a tetragonal prism having the dimensions $a_0 = 4.92 \text{ \AA.}$ and $c_0 = 11.64 \text{ \AA.}$ Hg atoms are at $(0,0,u)$, $(0,0,\bar{u})$, $(\frac{1}{2}, \frac{1}{2}, u + \frac{1}{2})$ and $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2} - u)$; I atoms at $(0,0,v)$, $(0,0,\bar{v})$, $(\frac{1}{2}, \frac{1}{2}, v + \frac{1}{2})$ and $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2} - v)$; u and v being approximately .117 and .353, respectively. The structure (Fig. 3) is thus built up of IHgHgI molecules, within which the Hg-Hg and Hg-I distances are approximately 2.72 \AA. and 2.75 \AA. , respectively.

These results are in good agreement with those obtained by others.

HYDROGEN GAS THERMOMETER COMPARED WITH THE OXYGEN AND HYDROGEN VAPOR-PRESSURE THERMOMETERS BY MEANS OF A COPPER-CONSTANTAN THERMOCOUPLE

BY W. F. GIAUQUE, H. L. JOHNSTON AND K. K. KELLEY¹

RECEIVED MAY 24, 1927

PUBLISHED OCTOBER 5, 1927

In connection with establishing a temperature scale for this Laboratory, a preceding paper² gives the results of comparison of copper-constantan thermocouples with the hydrogen gas thermometer from 15 to 283°K.

The present article presents results obtained by comparison of standard thermocouple W of Giaque, Buffington and Schulze (designated hereafter G., B. and S.) with the oxygen and hydrogen vapor-pressure thermometers.

The temperatures obtained from the oxygen vapor pressures as given by Cath³ are in very satisfactory agreement with those obtained from the thermocouple of G., B. and S. On the other hand, the results obtained by means of the hydrogen vapor-pressure measurements have fortunately

¹ National Research Fellow in Chemistry, University of California.

³ Cath, *Comm. Phys. Lab. Univ. Leiden*, 152d, 1918.

led to the prompt discovery of serious error in the hydrogen-gas thermometer results below 25°K. Our results indicate that considerable adsorption of the hydrogen gas must have taken place within the thermometer bulb, particularly at temperatures below the boiling point of hydrogen. This was not to be expected, since it had not been noted in the previous experience of others. The thermometer corrections for gas imperfection were taken from the work of Cath and Onnes⁴ in which duplicate bulbs containing hydrogen and helium, respectively, were kept in the same bath and differential pressures recorded. Corrections based on this method would include small adsorption effects. An important difference in the work of G., B. and S. was the use of a Pyrex glass thermometer bulb, whereas Cath and Onnes used one made from Jena glass.

The preparation of the Pyrex glass bulb used by G., B. and S. is perhaps worthy of comment. The bulb was blown and capillary tubing attached by means of a small opening which was left in the bottom until the bulb had been cleaned. Cleaning was accomplished by boiling in distilled water for some time, for one-half hour at least. The bulb was then dried by means of a stream of clean air and the bottom sealed off. We can remember no unusual surface condition resulting from the glass blowing but the apparatus has not been dismantled to confirm this.

There undoubtedly was a small amount of adsorbed water on the walls during the measurements, since the bulb was not heated during the pumping by the mercury diffusion pump. This adsorbed water could contribute no appreciable pressure, but is worth noting from the point of view of its possible effect on the character of the surface. At least until further work is carried out, the use of a Pyrex glass hydrogen thermometer below 25°K. must be regarded with suspicion. The most desirable change would be the use of helium gas.

Apparatus

The apparatus was that used by W. F. Giaque and R. Wiebe in an investigation to be published soon. Since the hydrogen thermometer described in the preceding paper was modeled after the above apparatus, the essential details and operation were practically identical, except that the thermometer bulb and the heavy cylinder which immediately surrounds it are replaced by a gold container connected with the exterior of the apparatus by means of a small glass tube with a platinum seal. The thermocouple was placed in the same manner as described in the preceding paper.

The pressure measurements were made in the same way, except that a manometer with tubes 1.6 cm. in diameter was used. All pressures are expressed in terms of international cms. of Hg. The gravitational

⁴ Cath and Onnes, *Comm. Phys. Lab. Univ. Leiden*, 156a, 1922.

acceleration used was 979.973 cm./sec.² as given by Sternwarte⁵ for this location.

Preparation of Oxygen

Electrolytic oxygen was prepared from a potassium hydroxide solution. It was freed from diffused hydrogen by passage over copper oxide maintained at 400°. The gas was then passed over amalgamated copper and solid potassium hydroxide. It was liquefied by means of liquid air and then fractionated, the middle third being used.

Oxygen Vapor-Pressure Results

The results of the oxygen vapor-pressure measurements are given in Table I, where they are compared with the temperatures given by the equation of Cath.³

$$\log_{10} P_{(\text{atmos.})} = \frac{-419.31}{T} + 5.2365 - 0.00648T \quad (1)$$

TABLE I
OXYGEN VAPOR-PRESSURE COMPARISON

P International cm. of Hg	T Equation (1)	T Thermocouple W
6.046	71.40	71.40
14.359	76.76	76.77
29.634	81.99	82.02
54.278	87.01	87.04
75.715	90.10	90.10

The agreement is better than we had expected and may indicate that the small deviations in the hydrogen gas thermometer comparison were due to the thermometer rather than to the thermocouple.

Preparation of Hydrogen

Electrolytic hydrogen was prepared in the manner described in the preceding paper, although in this case the purity is probably not important since impurities reasonably possible should not affect the vapor pressure appreciably.

Hydrogen Vapor-Pressure Results

The results of the measurements on hydrogen are given in Table II.

The readings of Thermocouple W are expressed in terms of Thermocouple Number 17 of G., B. and S. to facilitate comparison. The temperatures given in Col. 3 are calculated from the formula

$$\log_{10} P_{(\text{atmos.})} = -\frac{44.368}{T} + 1.6523 + 0.03240T - 0.0004189T^2 + 0.00000484T^3 \quad (2)$$

given by Martinez and Onnes.⁶

The thermocouple readings in the first two measurements given in Table II indicate too high a temperature, since a good vacuum had not

⁶ Martinez and Onnes, *Comm. Phys. Lab. Univ. Leiden*, 156b, 1922.

TABLE II
HYDROGEN VAPOR-PRESSURE COMPARISON

P International cm. of Hg	Thermocouple Microvolts	T Equation (2)	T Table III	T Calculated from data of G., B. and S.
2.687	6654.53	12.93 ^a	13.00	...
5.371	6650.52	13.92	13.96	(13.23)
31.090	6632.47	17.68	17.68	17.21
67.197	6619.60	19.95	19.96	19.66
74.822	6617.48	20.31	20.31	20.07
30.592	6632.80	17.64	17.62	17.14
30.984	6632.60	17.67	17.66	17.18
5.370	6650.71	13.92	13.91	(13.19)
5.368	6650.67	13.92	13.92	(13.20)

^a From equation (3).

been obtained when the readings were taken, and heat leak apparently influenced the thermocouple. The average value of the triple-point pressure, 5.370 cm., gives 13.92°K. as the temperature of the triple point. We have accepted this value in preference to the value of 13.95 given by Onnes and Gulik⁷ since there seems to have been some uncertainty as to the triple-point pressure (see Onnes and Keesom).⁸ However, our value for the triple-point pressure is in near agreement with that of Onnes and Braak,⁹ namely, 5.382 cm.

At 2.687 cm. pressure the hydrogen was solid and equation (2) could not be used. To find the temperature at this point the calorimetric data of Simon and Lange¹⁰ were used with the triple-point pressure and the temperature to obtain the equation

$$\log_{10} P_{(\text{cm.})} = \frac{-39.2}{T} + 2.70 \log T + 0.4584 \quad (3)$$

The procedure for obtaining equation (3) was to evaluate the two constants of Berthelot's equation of state by combining equation (2) with the thermodynamic equation $dP/dT = \Delta H/T\Delta V$ and the heat of vaporization data of Simon and Lange. With an equation of state thus established, combined with the calorimetric heat of sublimation and the assumption that infinitely dilute hydrogen gas would have the heat capacity of an ideal monatomic gas, equation (3) was readily obtained.

When the above thermocouple readings are compared with the data of G., B. and S. it is found that the temperatures given (Col. 5, Table II) are too low, which would be explained by adsorption in the gas thermometer. The character of the deviation makes the assumption of adsorption seem probable. Our values near the hydrogen boiling point

are rapidly approaching those of G., B. and S., indicating agreement a little above 25°K., while below the boiling point the effect rapidly increases, as would be expected. The agreement at 25°K. and in the range covered by the oxygen vapor pressures leads us to believe that the intermediate data of G., B. and S. are satisfactory.

The values given in Col. 4 are obtained by comparison with Table III,

30	6546.9		8.48	

which was constructed from the vapor-pressure data, and should be used to extend the table of G., B. and S. below 30°K.

It may be noted that no work based on the temperature scale of G., B. and S. has yet been published, so that the adsorption error encountered will result in no corrections to the literature.

Summary

One of the standard copper-constantan thermocouples described by Giaque, Buffington and Schulze in the preceding paper has been compared with the oxygen and hydrogen vapor-pressure thermometers.

Complete agreement, within the limits of accuracy, has been found with the Leiden scale at the temperatures of liquid oxygen.

The hydrogen vapor-pressure measurements have shown that the scale of G., B. and S. is in error below 25°K., apparently due to adsorption of hydrogen in the gas thermometer.

A table showing the behavior of a typical copper-constantan thermocouple below 30°K. has been given to extend that of G., B. and S.

The triple-point pressure of hydrogen was found to be 5.370 international cm. of Hg. This value, when combined with the vapor-pressure results of Martinez and Onnes, gives a triple-point temperature of 13.92°K.

An equation for the vapor pressure of solid hydrogen is included.

ACTIVITY COEFFICIENTS OF ELECTROLYTES. I A BI-BVALENT SALT AND THE ION ATTRACTION THEORY

BY ULRIC B. BRAY¹

RECEIVED MAY 25, 1927

PUBLISHED OCTOBER 5, 1927

Introduction

The ion attraction theory developed first by Milner,² and more recently by Debye and Hückel,^{3,4} has offered an apparently satisfactory explanation, at any rate at small concentrations, of the known behavior of strong electrolytes. The mathematical development of the theory shows why, and predicts how, the activity of an ion is related to the ionic strength. The equation for the activity coefficient γ of an ion with charge v as the ionic strength approaches zero is

$$\log \gamma = -Av^2 \sqrt{\frac{1}{2} \Sigma mv^2} \quad (1)$$

¹ National Research Council Fellow in Chemistry.

³ (a) Debye and Hückel, *Phys. Z.*, **24**, 185 (1923); (b) Debye, *ibid.*, **24**, 334 (1923).

⁴ For a clear and critical presentation of this theory see A. A. Noyes, *THIS JOURNAL*, **46**, 1080 (1924).

In this expression A is composed of certain universal constants, the dielectric constant, D_0 , of the solvent, and the absolute temperature. Using Drude's value, 78.77, for D_0 for water at 25° , the coefficient A becomes 0.505; using the recent value, 77.81, given by Kockel,⁵ A becomes 0.514. La Mer, King and Mason⁶ have obtained experimentally the value 0.528 for A from solubility measurements on the sparingly soluble tri-trivalent salt luteo-cobalt ferrocyanide and have calculated activity ratios for this salt which agree excellently with the theory.

In order to test the theory further with electrolytes of high-valence type, the activity coefficients of the bi-bivalent salt zinc sulfate were determined through electromotive-force measurements. Using the cell

measurements were made over the concentration range from 0.0006 to 3.4 molal. The electromotive force E of the cell in terms of its electromotive force E_0 when the activities of the zinc and sulfate ions are 1 molal is related to the mean activity coefficient of the ions of the salt $\sqrt{\gamma_{\text{Zn}} \gamma_{\text{SO}_4}}$ and to its molality, m , as follows

$$E = E_0 - 0.059150 \log m \sqrt{\gamma_{\text{Zn}} \gamma_{\text{SO}_4}} \quad (2)$$

For the convenience in plotting and calculating the mean activity coefficient we shall calculate the value of the quantity E'_0 defined by the equation

$$E'_0 = E + 0.059150 \log m \quad (3)$$

Combined with (2) this gives

$$E'_0 = E_0 - 0.059150 \log \sqrt{\gamma_{\text{Zn}} \gamma_{\text{SO}_4}} \quad (4)$$

From Equation 1, using Kockel's value for D_0 , we get for the bivalent salt

$$\log \sqrt{\gamma_{\text{Zn}} \gamma_{\text{SO}_4}} = -4.11 \sqrt{m} \quad (5)$$

Combining this with (4), we obtain

$$E'_0 = E_0 - 0.243 \sqrt{m} \quad (6)$$

It is evident that a plot of E'_0 against m should, as zero concentration is approached, give a straight line with slope -0.243 , and that the correct extrapolation of the curve to zero will give E_0 . Since the approach to linearity and the final slope constitute the test of the limiting equation, it was the author's purpose to determine this slope more accurately and with less uncertainty than has previously been possible from electromotive-force or freezing-point data.

Apparatus and Method

The Cell and Electrodes.—Although the attempts of some previous investigators^{7,8} to use a lead-lead sulfate electrode were unsuccessful,

⁸ Horsch, *ibid.*, 41, 1788 (1919).

Henderson and Stegeman⁹ obtained very constant and reproducible results with the cell

A careful study of lead-lead sulfate electrodes was made by the present author, which led to the following conclusions: (1) oxygen must be excluded from the cell; (2) a definite, crystalline form of lead sulfate is essential; (3) equilibrium between the solid lead sulfate and the solution

is best established before the electrode is made up; (4) the use of a two-phase amalgam is desirable.

Fig. 1 shows diagrammatically the cell vessel used. The tubes marked N permitted nitrogen to be passed through the solution and were connected to glass manifolds by bits of rubber tubing carrying screw pinch-cocks for equalizing the flow of gas in the different electrodes. A mercury trap on the outlet manifold prevented the diffusion of air into the cell when the flow of nitrogen was stopped. The passage of nitrogen through the cell served the double purpose of removing oxygen and of stirring the contents of the cell above the amalgams. The platinum wires sealed into the bottoms of the electrodes were fused to copper wires, eliminating the inconvenient use of mercury for electrical contacts to the measuring system. By using fairly small platinum wire, 0.4 mm. diameter, platinum-Pyrex seals may be made to hold satisfactorily. During the course of the experiments there has been no difficulty encountered from leakage through these seals.

Fig. 1.

Since the preparation of a satisfactory sulfate electrode for use in dilute solution requires attention to certain details, it seems desirable to describe the technique employed. The zinc sulfate solution to be used was first divided into two parts. To one part was added several grams of lead sulfate previously washed with the same solution, and the mixture

⁹ Henderson and Stegeman, *THIS JOURNAL*, 40, 84 (1918).

in a 1-liter, glass-stoppered, Jena glass bottle was rotated for 12–15 hours. At the end of this time, the electrode vessel, which had been dried at 115° , was filled with nitrogen by running a rapid stream of the gas through it for 5–10 minutes. The two-phase amalgams were heated until they became one-phase and were pipetted into the electrode vessel. Pyrex pipets of about 15 cc. capacity with an ungreased stopcock on the lower tube were used. A stream of nitrogen was passed through the cell while the amalgams cooled to room temperature. The half of the vessel containing the lead amalgam was filled with the solution saturated with lead sulfate after a layer of lead sulfate from the bottom of the flask had been pipetted onto the lead amalgam. The half containing the zinc amalgam was filled with the remainder of the solution which had not been saturated with lead sulfate. Large stopcocks and short tubes at S made it possible to make readings with the stopcocks closed in all but the two lowest concentrations. At these concentrations the initial level of liquid in the zinc side was made higher than in the lead side in order that when the stopcocks were opened for a reading the slight flow of solution would be from zinc to lead and never the reverse. After the cell had been placed in the thermostat, nitrogen was passed through for two hours. At the end of this time the cell had reached the temperature of the thermostat and its electromotive force was generally within less than a millivolt of the final constant reading.

The cell vessel (Fig. 1) is composed of six electrodes divided into two groups of three by the two stopcocks, S. On the one side, three similar lead sulfate electrodes were made and, on the other side, three zinc electrodes. The six external wires were connected to the potentiometer through a switchboard which permitted any pair of electrodes to be compared. The triplicate lead and triplicate zinc electrodes furnished a convenient and satisfactory check on the constancy and the reproducibility of the cell. In all of the experiments the zinc electrodes were found to check each other within 0.03 millivolt, and the sulfate electrodes to within 0.04 millivolt. Readings were taken on each cell over at least 36 hours after the cell had reached its final value (which was generally within six hours after the cell was made); and the degree of constancy obtained was such that the average reading of the combinations remained constant to within 0.04 millivolt over this period of time. In some of the experiments the cells were allowed to remain in the thermostat for a week before the divergence from the mean became as great as 0.2 millivolt.

In all solutions below 0.02 molal, another check on the cells was made by pipetting off the solution above the amalgams after the cell had been read for two days and introducing fresh solution. In four or five hours the cell would always come back to its previous reading.

Analysis of Zinc Solutions.—For experiments below 1 molal concen-

tration two stock solutions of zinc sulfate were used. Into a weighed quantity of solution, a sufficient quantity of redistilled water was weighed. The stock solutions were analyzed by titrating potentiometrically with potassium ferrocyanide solution (twentieth molal, to each liter of which had been added 1 g. of potassium ferricyanide). A bright platinum wire and calomel electrode comprised the electrodes. A weighed sample of the solution was made acid with 5 cc. of 4 *N* sulfuric acid, diluted to 250 cc., heated to 70° and stirred while the titration was being made. With reasonable care this method of zinc analysis is good to 0.1%; often three or four check analyses will have a deviation of less than 0.05%. The potassium ferrocyanide solution was standardized, first, against Kahlbaum's "zur Analyse" zinc sticks scraped clean; second, by titrating the zinc sulfate

Fig. 2.—The zinc-lead cell at small concentrations.

residue left in a weighed platinum dish upon evaporation of a concentrated solution of zinc sulfate and heating the dish to 500°. The first method is the more exact but the second method was found to check to within 0.2%.

The Measurements.—All measurements were made at $25.00 \pm 0.01^\circ$ in an oil-bath heated with a nichrome coil. The potentiometer was a Leeds and Northrup type K with Leeds and Northrup galvanometer No. 2500 B of resistance 460 ohms. The Weston standard cell used was checked at regular intervals against the laboratory standard cell.

Preparation of Materials

Lead Nitrate.—Merck's best grade of c. p. salt was recrystallized three times from hot water and the crystals were dried in air.

Lead Sulfate.—Since the lead sulfate was to be used in zinc sulfate solution, it was considered advisable to precipitate the lead sulfate with zinc sulfate. To a 5% solution of lead nitrate, made from the purified lead nitrate, was added an excess of a 10% solution of purified zinc sulfate. The liquid with its precipitate was heated to boiling

and boiled for fifteen minutes, after which time the lead sulfate had assumed a definite, crystalline form. The lead sulfate was washed ten times by decantation and drained on a Buchner funnel. The material was then transferred to a wide-mouthed bottle and kept under distilled water until used. The author has found that in any case where a solid material is to be used for electrodes it is advisable to keep the material under water until it is used.

Zinc Sulfate.—The best grade of $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ was recrystallized three times from hot water. According to Mellor¹⁰ the maximum solubility of zinc sulfate is at 70°. The heptahydrate obtained on slowly cooling the solution was partially dried in air.

Lead Amalgam.—Into mercury which had been carefully purified¹¹ lead was electrolyzed from a solution of lead nitrate. The anode consisted of platinum foil placed in another beaker filled with 1 *N* HNO_3 , and connected to the first beaker by means of a Y-tube. A paddle stirrer was placed in the mercury in the cathode beaker so as to slowly stir the mercury during the electrolysis. The current was 0.1 ampere and was run until the concentration of lead in the amalgam was about 3%. The amalgam was washed, dried and heated until it became one-phase and filtered through a capillary tube into an evacuated flask which was then filled with nitrogen.

Zinc Amalgam.—Sticks of Kahlbaum's "zur Analyse" grade of zinc were purified by rapid electrolysis with 3–4 amperes. The zinc crystals were washed, drained and weighed moist. A weighed quantity of mercury corresponding to 3% zinc was added to the moist crystals; the mass was then covered with a dilute solution of nitric acid and stirred until all the zinc crystals had gone into the amalgam. After washing, drying, heating and filtering through a capillary tube into a vacuum the amalgam was stored under nitrogen in the same way as the lead.

Nitrogen.—Tank nitrogen was purified by the van Brunt method.¹² The gas after leaving the dilute sulfuric acid wash bottle was dried by passing through a tower filled with soda lime. Passing through a three-way stopcock, the gas was used dry or led into a bubbler filled with a zinc sulfate solution of the concentration used in the cell and thence into the cell vessel.

The Experimental Data

In Table I are given the experimental data and the calculated function E'_0 . The observed electromotive forces given in Col. 2 are in every case the average of the combination of the six electrodes described above.¹³

¹² Van Brunt, *THIS JOURNAL*, **36**, 1448 (1914).

¹³ A correction for the solubility of lead sulfate was made at the concentrations of 0.003 *M* and less. This was done by calculating the increase in sulfate-ion concentration in the solution coming from the solubility of lead sulfate, and by obtaining the corresponding potential resulting therefrom by means of the usual equation $E = 0.0296 \log c_1/c_2$. Böttger (*Z. phys. Chem.*, **46**, 804 (1903)) found the solubility of lead sulfate at 25° to be 1.34×10^{-4} *M*. From the limiting ion attraction equation, γ is found to be 0.88 at this concentration, so that the solubility product of lead sulfate is 1.39×10^{-8} . From the quadratic equation $(\gamma m + x)x = 1.39 \times 10^{-8}$, by substituting the values of γ calculated from the limiting equation, the value of the increase x in the sulfate-ion concentration due to the lead sulfate was obtained and, by completing the calculations indicated above, we get the following corrections which have been added to the observed voltages: 0.0033 *M*, 0.00004 v.; 0.0016 *M*, 0.00012 v.; 0.0015 *M*, 0.00013 v.; 0.00069 *M*, 0.00055 v.; 0.00067 *M*, 0.00058 v.; 0.00066 *M*, 0.00059 v.
